- **Microbiota** e **microbioma** sono due termini spesso usati come sinonimi. Ma non lo sono. Nella maggior parte dei casi questo utilizzo “intercambiabile” non compromette la comprensione del testo, tuttavia è importante riflettere sulla profonda **differenza di significato** tra le due parole.

- Microbiota si riferisce a una **popolazione di microrganismi** che colonizza un determinato luogo.
- Il termine microbioma invece indica la totalità del **patrimonio genetico** posseduto dal microbiota, cioè i geni che quest'ultimo è in grado di esprimere.

THE MICROORGANISMS LIVING ON AND IN US INCLUDE...

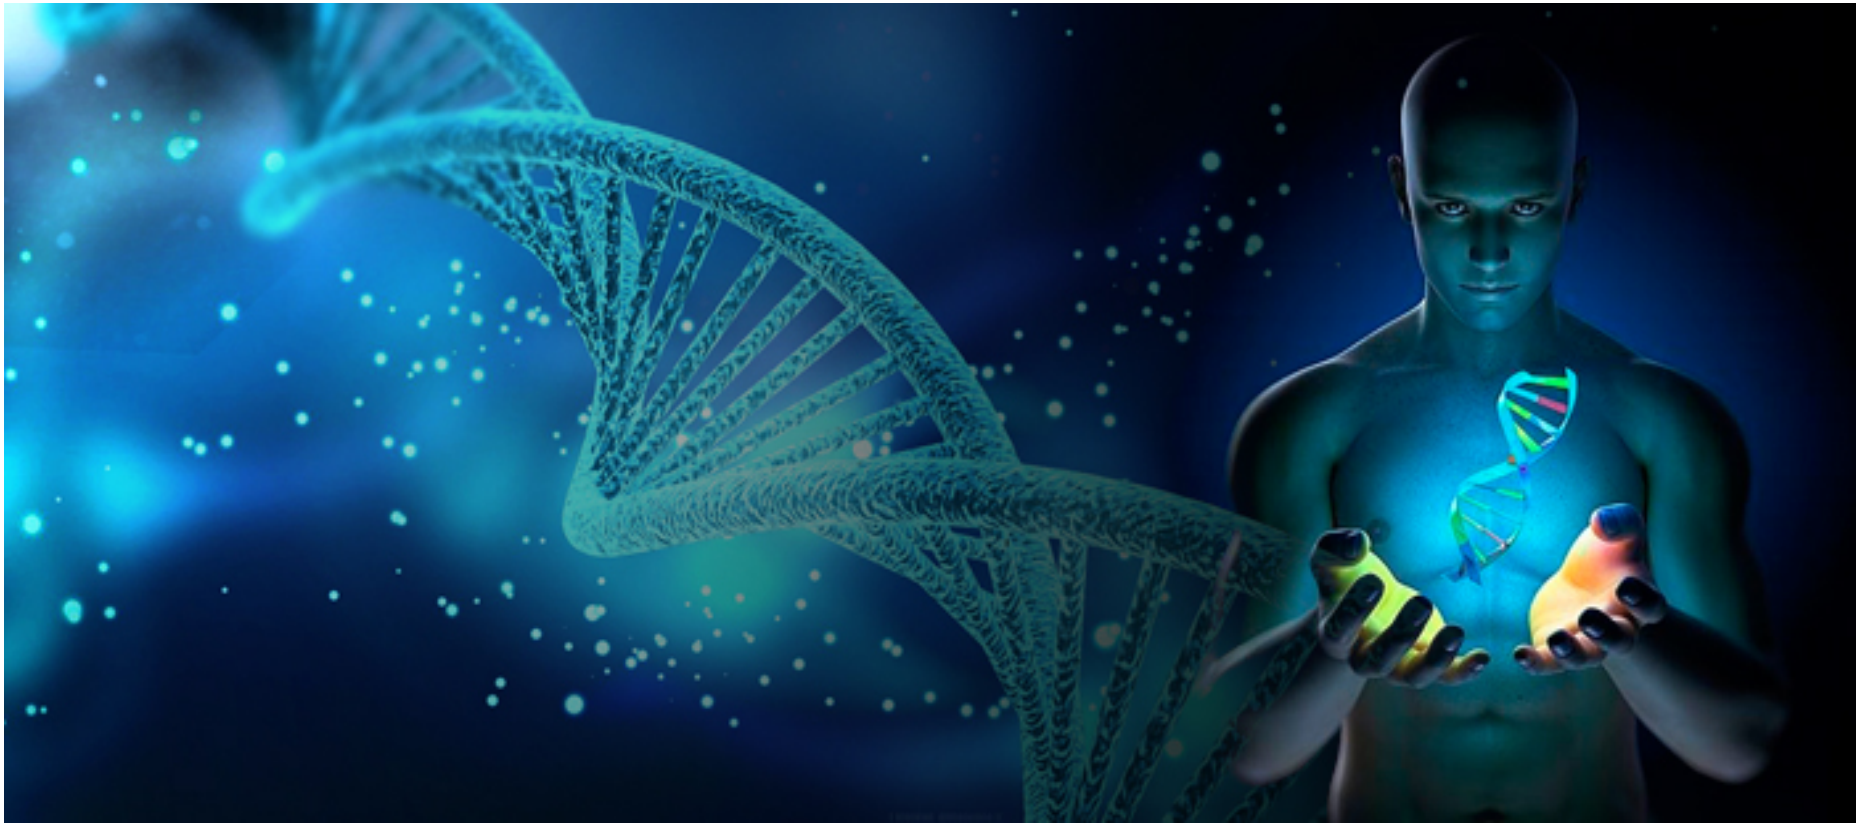
- Quando si parla di microbiota si fa riferimento alla totalità dei singoli **microrganismi** – batteri, funghi, archeobatteri e protozoi – e dei **virus** che vivono e colonizzano uno specifico ambiente in un determinato tempo, vivendo in simbiosi con il corpo umano .
- Tutto il corpo ospita differenti nicchie microbiotiche per un totale di circa **38.000 miliardi di batteri**. Le tribù (chiamati phyla) più abbondanti sono *Firmicutes* e *Bacteroidetes*.

- Il termine microbioma indica invece la totalità del **patrimonio genetico** posseduto dal microbiota, cioè i geni che quest'ultimo è in grado di esprimere.
- Se consideriamo il **microbioma umano**, tali geni codificano per alcune molecole che il corpo non riesce a produrre autonomamente : Il **99%** della nostra componente genetica deriva dai batteri, che rappresentano un **secondo genoma aggiuntivo simbiotico** .

Patrimonio genetico umano: circa 20 mila geni



Patrimonio genetico batterico: circa 20 milioni di geni milioni di geni

Possiamo affermare che abbiamo 2 genomi:

- Primo (fisso e immutabile) ereditato dai genitori
- Secondo (molto più dinamico) acquisito dai batteri che compongono il Microbiota

Possiamo classificare i microbioti in :

-***Primari*** : fecale, vaginale, orale, cutaneo e nasale

-***Derivati*** : polmonare, endometriale, vescicale, mammario, intestinale fetale

I microbioti sono interconnessi e le interconnessioni sono strutturate :

- all'interno dell'ospite
- tra ospiti
- con l'ambiente circostante (terreno , atmosfera , cibo e animali)

- L'intervento sui microbioti primari influenza l'eubiosi del microbiota secondario, attuare una terapia batterica indicata per il microbiota primario, di conseguenza, ci darà vantaggi per quello secondario

- L’intervento con lo Streptococcus salivariusK12 nel cavo orale ci darà vantaggi anche sul microbiota polmonare e placentare
- L’intervento con il Lactobacillus crispatusM247 sul microbioma intestinale porterà vantaggi all’ambiente vaginale e di conseguenza anche a quello endometriale e vescicale.

Microbial transmission in NCDs?

The microbiota of an individual is affected by environmental factors such as diet, smoking, alcohol intake, and exercise. Dysbiotic microbiota can influence NCDs or their risk factors, such as obesity, and might be transmitted between individuals, potentially contributing to the spread of disease.

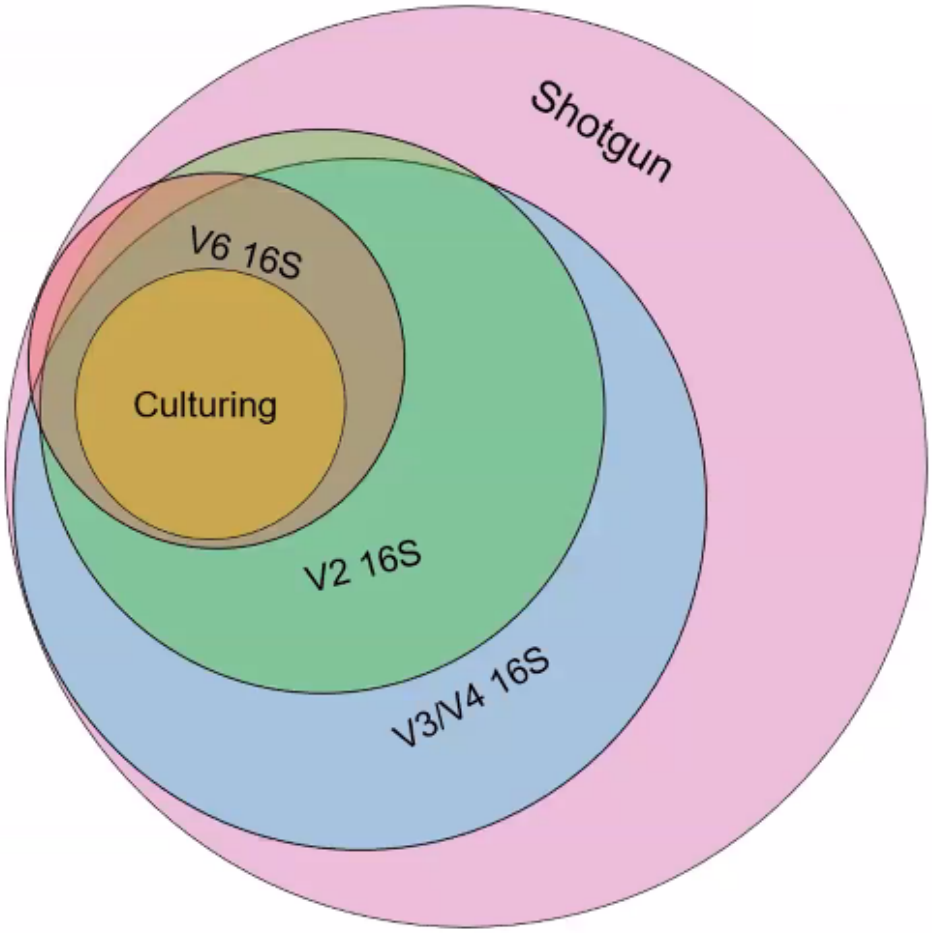
TASSONOMIA BATTERICA

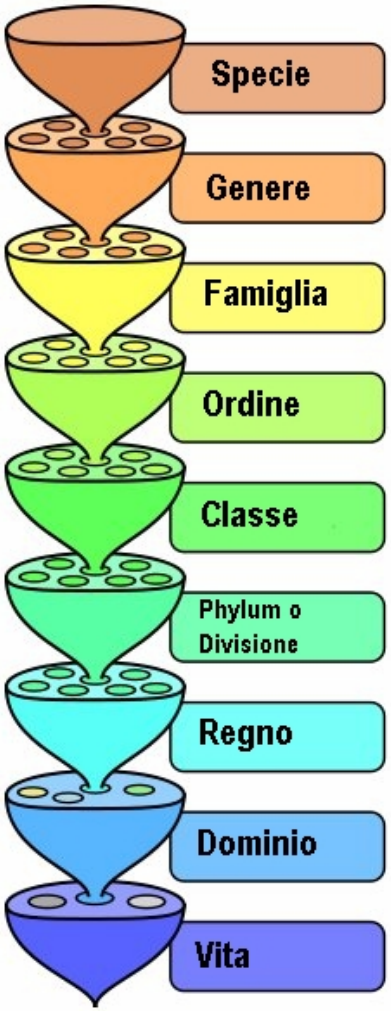
Tecniche colturali

NGS



- Se oggi possiamo studiare (sebbene solo per quanto riguarda la parte batterica) la composizione del microbiota lo dobbiamo alla **metagenomica**, la quale basa le proprie indagini sul microbioma.
- In particolare, l'esame in grado di indagare la popolazione batterica è il **sequenziamento genomico del 16S rRNA**, un gene dell'RNA specifico di ogni batterio che serve a produrre i ribosomi, responsabili della sintesi proteica. Identificarlo significa risalire alla singola specie batterica.

TECNICHE DI SEQUENZIAMENTO GENOMICO

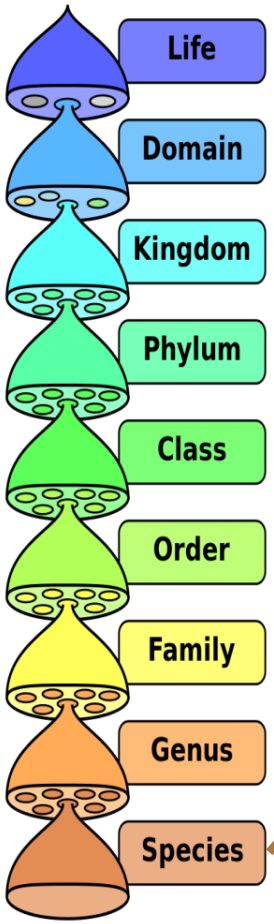


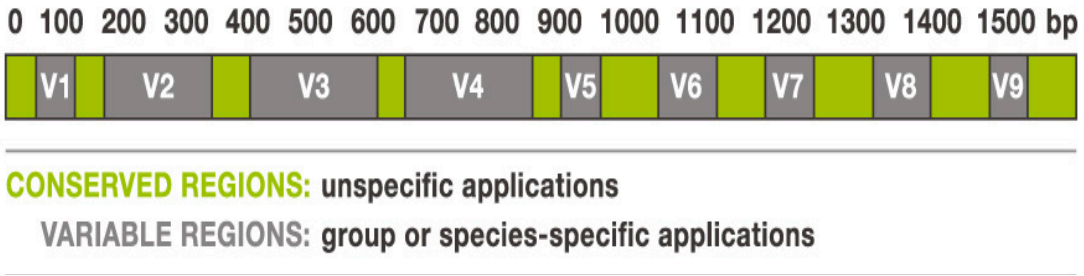
Mediante l'uso del gene 16 SrRNA, unico per ora che identifica i procarioti quali sono i nostri batteri intestinali.

Le tecniche genomiche hanno permesso di:

- Identificare altre popolazioni batteriche presenti nell'intestino
- Di raggruppare in Phylum (tribù) gli ordini e le specie

16S ribosomal RNA gene sequences





- The 16S rRNA is part of the 30S (small) subunit of the ribosome. Its sequence is highly conserved.
- The 16S rRNA has blocks of conserved regions (green blocks) interspersed with variable sequences (grey). This makes designing primers for PCR amplification possible.
- Due to this conservation across the genus *Bacteria* it is possible to **design primers that can amplify any bacterial species.**
- <u>Bacterial taxonomy based on 16S rRNA sequence:</u> Variable regions are nearly identical within species, but also similar within a genus and family. **Therefore, analysis can be performed to identify the genus (e.g. *Bacteriodes*), species (*Bacteriodes fragilis*).**

Abbiamo identificato un specifico microbioma placentare unico, composto da:
Firmicutes, Tenericutes, Proteobacteria, Bacteroidetes e Fusobacteria phyla.

i profili del microbioma placentare erano più affini (dissomiglianza <0,3) al microbioma orale umano.

⇒ Burkholderia, Actinomycetales e Alphaproteobacteria erano preponderanti tra le gravide pretermine

⇒ Paenibacillus era preponderante nei campioni placentari a termine

Il microbioma ha un ruolo centrale nella regolazione del metabolismo, della funzione immunitaria e del comportamento nell'uomo.

È diventato chiaro che la placenta non è un organo sterile, ma ha il suo microbioma endogeno.

La composizione del microbioma placentare è diversa da quella della vagina mentre si sovrappone, come specie batteriche, al microbioma orale.

Viable bacterial colonization is highly limited in the human intestine in utero

Mucosal immunity develops in the human fetal intestine by 11–14 weeks of gestation, yet whether viable mi and interact with the intestinal immune system is unknown. Bacteria-like morphology was identified in po meconium at mid-gestation by scanning electron microscopy ($n = 4$), and a sparse bacterial signal was de sequencing ($n = 40$ of 50) compared to environmental controls ($n = 87$). Eighteen taxa were enriched in f Micrococcaceae ($n = 9$) and *Lactobacillus* ($n = 6$) the most abundant. Fetal intestines dominated by Micro distinct patterns of T cell composition and epithelial transcription. Fetal *Micrococcus luteus*, isolated onl monocytes, grew on placental hormones, remained viable within antigen presenting cells, limited inflan possessed genomic features linked with survival in the fetus. Thus, viable bacteria are highly limited in t mid-gestation, although strains with immunomodulatory capacity are detected in subsets of specimens.

Un andamento cronico e protratto nel tempo può determinare una pericolosa disbiosi

- Establishment of complete colonisation at birth, primarily in the gut, and the gradual diversification into a stable microbial ecosystem during infancy, is essential for this symbiotic relationship to develop

- At the age of 2-5 years, the gut possesses a microbial profile, which fully resembles ‘adult-like’ microbiota in terms of composition and diversity
- Optimal symbiosis may profoundly help to maintain health throughout infancy and childhood and a complete colonisation and development of the microbiota during early life play important roles in maintaining health during infancy , childhood and adult life .

- The most important perinatal environmental factors that largely affect the developing infant microbiota are pre- and postnatal medical treatments, including caesarean delivery, maternal intrapartum antibiotic prophylaxis (IAP) and postnatal infant antibiotic treatment , hospitalisation post birth and formula feeding

"Development of intestinal microbiota in infants and its impact on health"S. Matamoros et al., review in Trends in Microbiology, 2013.

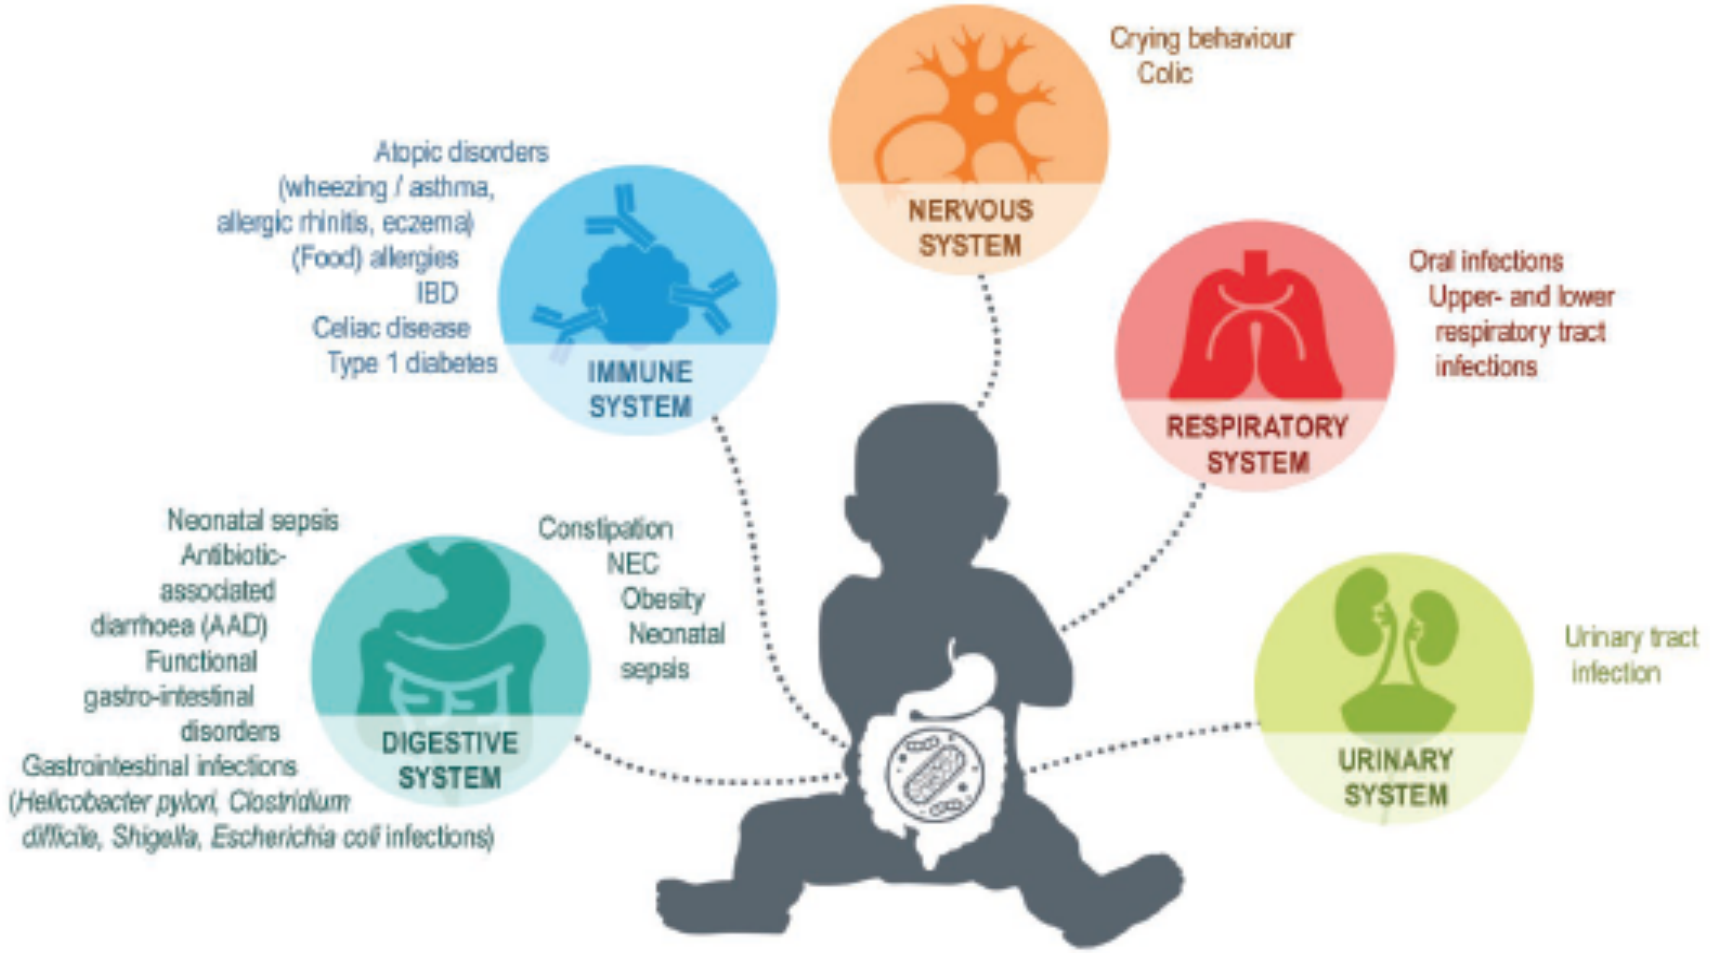

Figure 1.1. The interplay between microbiota, body systems and paediatric diseases. The human microbiota are important for the development and functioning of various physiological systems in the child's body, including the digestive system, immune system, nervous system, urinary system and respiratory system. Disruption of microbial communities may thus affect the child's health and behaviour.

QUALE E’ IL RUOLO DEL MICROBIOTA

- Conoscere il microbiota e le sue funzioni comporta **un cambiamento di prospettiva**: l'uomo appare come un **ecosistema** costituito da un aggregato di geni umani e geni microbici; il nostro metabolismo e quello delle specie che ci abitano si intrecciano, interagiscono ed evolvono parallelamente.

- Il microbiota dovrebbe essere considerato come **un vero e proprio organo metabolico** squisitamente convertito alla nostra fisiologia, che si occupa di funzioni che non siamo in grado di svolgere altrimenti.

- Tali **funzioni** includono la capacità di assimilare componenti altrimenti indigeribili della nostra dieta, sintetizzare alcune vitamine indispensabili, disgregare e detossificare sostanze che il nostro organismo non è in grado di smantellare, regolare l'espressione del sistema immunitario (di cui, non a caso, il 70% risiede nell'intestino), proteggere la mucosa intestinale dall'attacco di specie patogene.

- L’influenza del microbiota nella regolazione dell’**attività metabolica** è oggi riconosciuta con sempre più evidenze a supporto. Allo stesso modo, è stato scoperto anche un impatto del microbiota sugli **stati psicologici** per via dell’influenza sull’asse ipotalamo-ipofisi-surrene e sul sistema serotoninergico.

- Un’altra caratteristica del microbiota umano è il ruolo nello sviluppo del **sistema immunitario** durante la prima parte dell’infanzia e, di conseguenza, sullo stato di infiammazione del corpo.

ROLE OF BACTERIA WITHIN HUMAN HEALTH

- They help with human digestion
- They help with metabolism
- They manufacture vitamins
- They produce neurochemicals
- They interact with our hormones
- They interact with our nervous system
- They have anti-infective properties
- They are integral to our immune system

Il Microbiota sostiene e promuove importanti funzioni:

1. Produzione di enzimi, favorendo così i processi digestivi
2. Decomposizione fermentativa degli zuccheri con produzione di acidi organici e anidride carbonica
3. Decomposizione putrefattiva dei residui proteici con produzione di fenolo, indolo, cresolo, ammoniaca e acido solfidrico
4. Metabolizzazione dei grassi e regolazione plasmatica di colesterolo e trigliceridi
5. Sintesi di vitamine (vitamina K, B1, B6, B12, PP, Acido Folico e Acido Pantotenico)
6. Produzione di acidi grassi a catena corta, come l'acido acetico, propionico e butirrico
7. Decomposizione degli Acidi Biliari, Bilirubina e Ormoni Steroidei
8. Produzione di sostanze ad azione antimicrobica
9. Modulazione del sistema immunitario
10. Potenziamento della funzione di barriera intestinale, contro l’invasione di batteri patogeni
11. Regolazione della motilità del tubo digerente e della composizione dei gas intestinali e delle feci
12. Regolazione del pH dell’ambiente gastrointestinale.

- Batteri della stessa specie possono svolgere funzioni molto diverse, e addirittura all'interno della stessa specie possiamo ritrovare **ceppi molto patogeni** e **ceppi assolutamente salutari** (come nella Escherichia coli).

EUBIOSI:
EU = BUONA & BIOS = VITA / SALUTE

- Uno stato di equilibrio tra i batteri buoni e i batteri dannosi (eubiosi) è quindi fondamentale per garantire il buon funzionamento di tutto l'organismo.
- Microbiota ed Ospite , in qualunque nicchia biologica si incontrino , convivono mediante un modello di aggregazione cooperativo
- E' necessaria una corretta biodiversità , una adeguata ricchezza ed abbondanza delle diverse specie per ottenere uno stato di equilibrio microbico del microbiota che si traduca solo in effetti positivi per salute dell'organismo ospite .

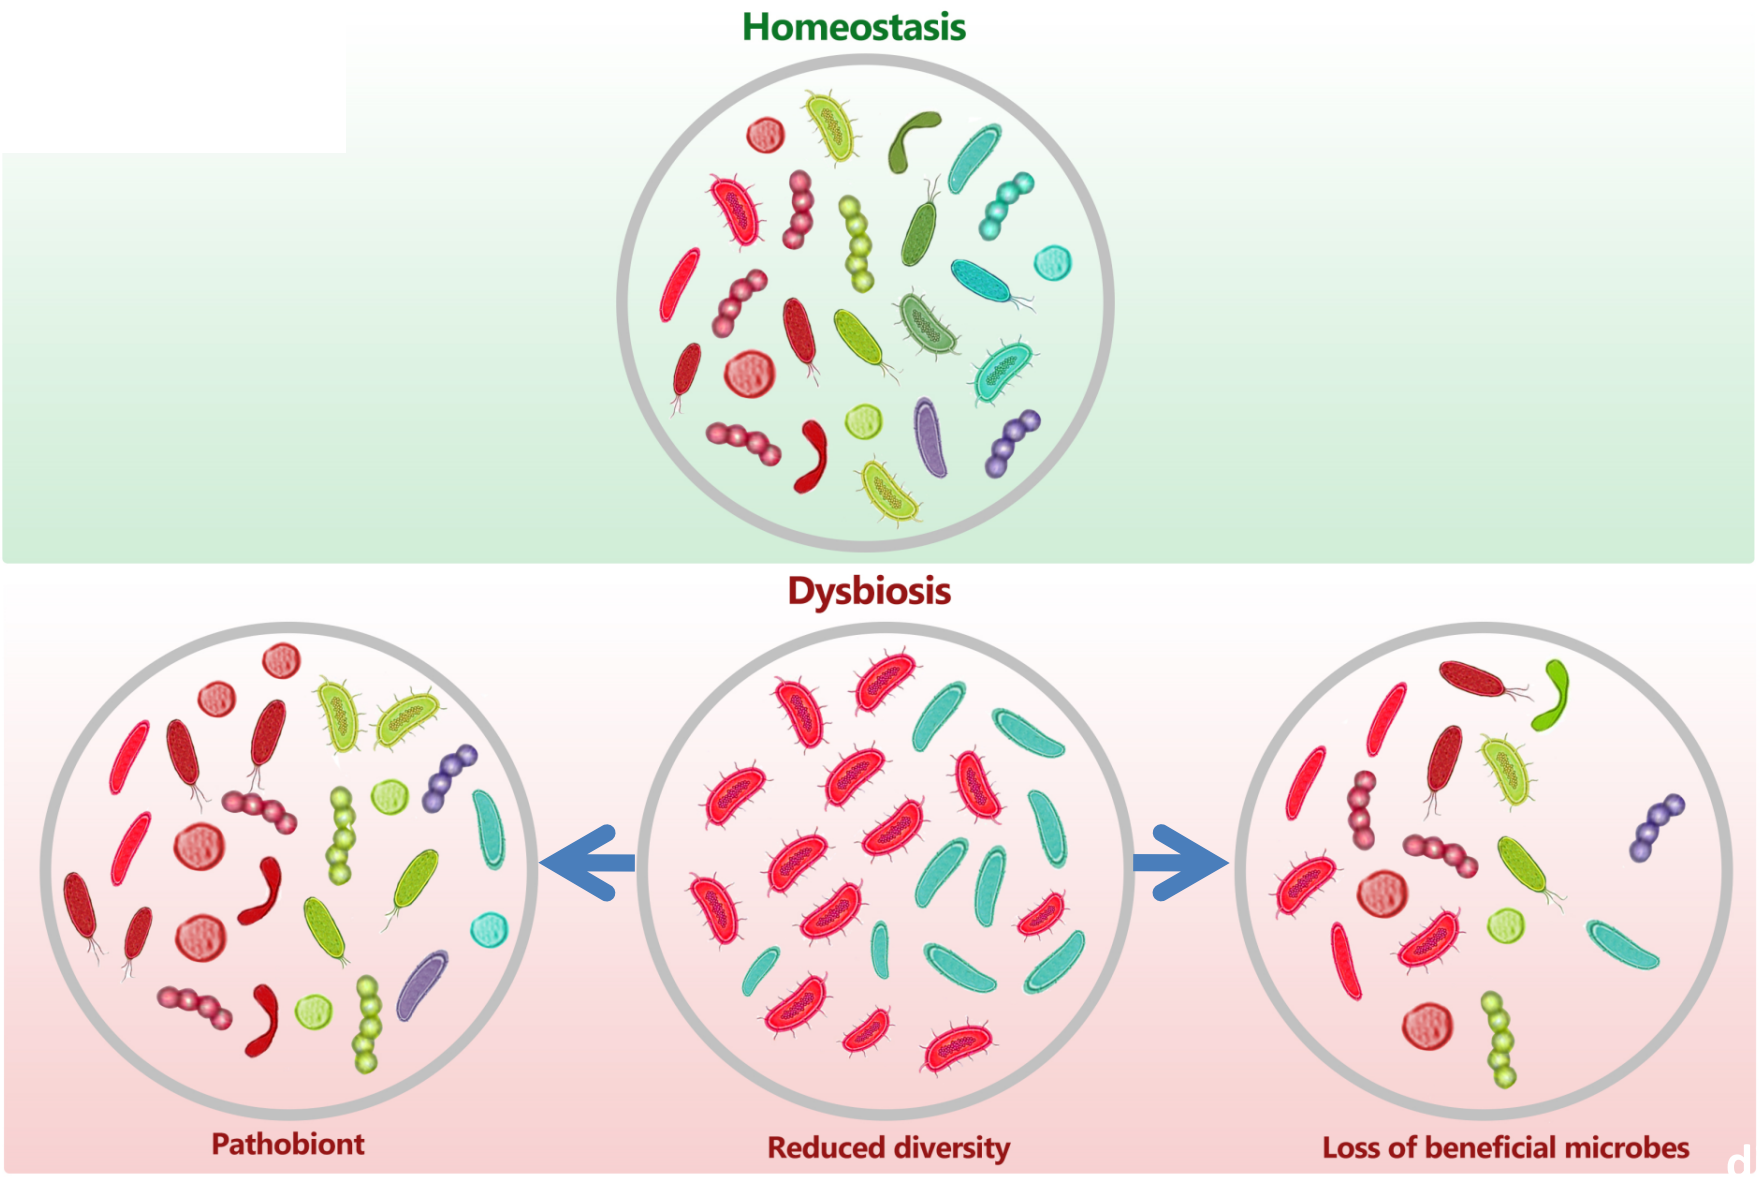
- Ogni volta che questo equilibrio si interrompe si crea invece una **disbiosi**. Nella condizione di disbiosi non solo viene meno la codifica genica delle molecole utili, ma vengono in parte metabolizzati composti dannosi da parte dei microrganismi patogeni, anch'essi parte del microbiota.

Eubiosi vs disbiosi



- I **fattori** che possono influenzare il microbiota in età adulta sono i più diversi: fattori ambientali, stress, assetto ormonale (come in gravidanza, in menopausa, o nel periodo premestruale), terapie farmacologiche; anche il cibo ha un ruolo centrale nel determinare la composizione individuale del microbiota.

- La rottura di questo equilibrio del microbiota (**disbiosi**) è all'origine di molti stati patologici del sistema digerente , (intestino irritabile, stipsi o diarrea, infiammazioni intestinali ,Sartor 2008)
- Si osserva la comparsa di malattie legate alla sfera immunologica, allergie, patologie autoimmuni, sovrainfezioni batteriche che possono essere la fonte di infezioni recidivanti ricorrenti dell'apparato urinario (cistiti, vaginiti, prostatiti)o di insufficienza renale cronica (Koeth 2013

- Si osserva la comparsa anche di patologie metaboliche (insulino-resistenza, ipercolesterolemia, obesità) (Ridaura 2013) e di importanti disturbi comportamentali e dell'umore (irritabilità, depressione, autismo) (Toh 2015; Hsiao 2013).

- Let's say you have ten diseases that are rising at the same time. Each one might have a separate cause. Or, perhaps, there's one thing that's fuelling them all, that's causing all of them to rise. One possible reason is a change in our microbiome, in what I've called Missing Microbes, or The Disappearing Microbiota Hypothesis.

- That our ancient microbiome, which protected us against many diseases, is degrading. And with that degradation, these diseases are being fuelled.

Mission - generating resources that would enable the comprehensive characterization of the human microbiome and analysis of its role in human health and disease

- the Human Microbiome Project has enabled the study of the structure and composition of the microbiome at different body sites, revealing that the female reproductive tract microbiota accounts for approximately 9% of the total bacterial load in humans.

Deciphering the effect of reproductive tract microbiota on human reproduction

Inmaculada Moreno| Carlos Simon

- The microbiome of the vagina in healthy reproductive-age women presents a biomass of approximately one billion bacteria per gram of vaginal fluid with low diversity, mainly composed of one or few *Lactobacillus* species, representing 90%-95% of the total bacteria in the reproductive tract.

- The human vaginal microbiota is a key component in the defense system against microbial and viral infections, conferring protection against disease (Turovskiy et al., 2011).
- The vaginal microbiome is dominated by many species including *Lactobacillus and members of the Clostridiales, Bacteriodales, and Actinomycetales(Aagaard et al., 2012).*

- This community , however , predominantly comprises *Lactobacilli* in healthy women, although other genera have been identified, namely, *Prevotella*,*Gardnerella*, *Atopobium*, *Sneathia*, *Bifidobacterium*, *Megasphaera*, and *Anaerococcus*

- This is an interesting finding unique to the human reproductive tract microbiome, as other mammals present a vaginal microbiota not dominated by *Lactobacillus*.

- the bacterial communities in the reproductive tract play important roles at different stages of the reproductive process, starting with gamete formation, fertilization, pregnancy establishment and maintenance and even the microbial colonization of the newborn

- Based on this concept, various studies have sought to define the features and composition of a “normal/healthy” microbiome and establishing the potential shifts leading to a “dysbiotic/abnormal” microbiota.

- The first description of the vaginal microbiome in a set of 396 reproductive-age women using NGS for the 16S rRNA bacterial gene revealed the existence of five distinct community state types (CSTs) depending on the abundance of the bacteria identified. CST-I, -II, -III, and -V are dominated by *Lactobacillus crispatus*, *Lactobacillus gasserii*, *Lactobacillus iners*, and *Lactobacillus jensenii*, respectively.

- More than 70% of women demonstrated vaginal microbiota dominated by L. crispatus, L. gasseri, L. iners, or L. jensenii, corresponding to CST-I, -II, -III, and -V.
- A smaller proportion of women exhibit CST-IV, characterized by lower percentage of Lactobacilli and dominance of anaerobic bacteria including Aerococcus, Atopobium, Dialister, Gardnerella, Megasphaera, Prevotella, and Sneathia

BACTERIAL VAGINOSIS : Amsel criteria

In clinical practice BV can be diagnosed using the Amsel criteria:

- Thin, white, yellow, homogeneous discharge
- Clue cells on microscopy
- pH of vaginal fluid >4.5
- Release of a fishy odor on adding alkali—10% potassium hydroxide (KOH) solution.
- At least three of the four criteria should be present for a confirmed diagnosis.[34] A modification of the Amsel criteria accepts the presence of two instead of three factors and is considered equally diagnostic.

BACTERIAL VAGINOSIS :
Nugent score

- The Nugent Score is more used by physicians even if it takes much time to read the slides and requires the use of a trained microscopist. A score of 0-10 is generated from combining three other scores. The scores are as follows:
- 0–3 is considered negative for BV
- 4–6 is considered intermediate
- 7+ is considered indicative of BV.
- At least 10–20 high power (1000× oil immersion) fields are counted and an average determined.

- Based on Nugent score, CST-IV represents the most common dysbiosis state *i.e. bacterial vaginosis* .
- However, this state was also found to be reported in various healthy individuals, predominantly (40%) in black and Hispanic women : it is still debateable whether this CST represents a healthy state or an asymptomatic state of BV.

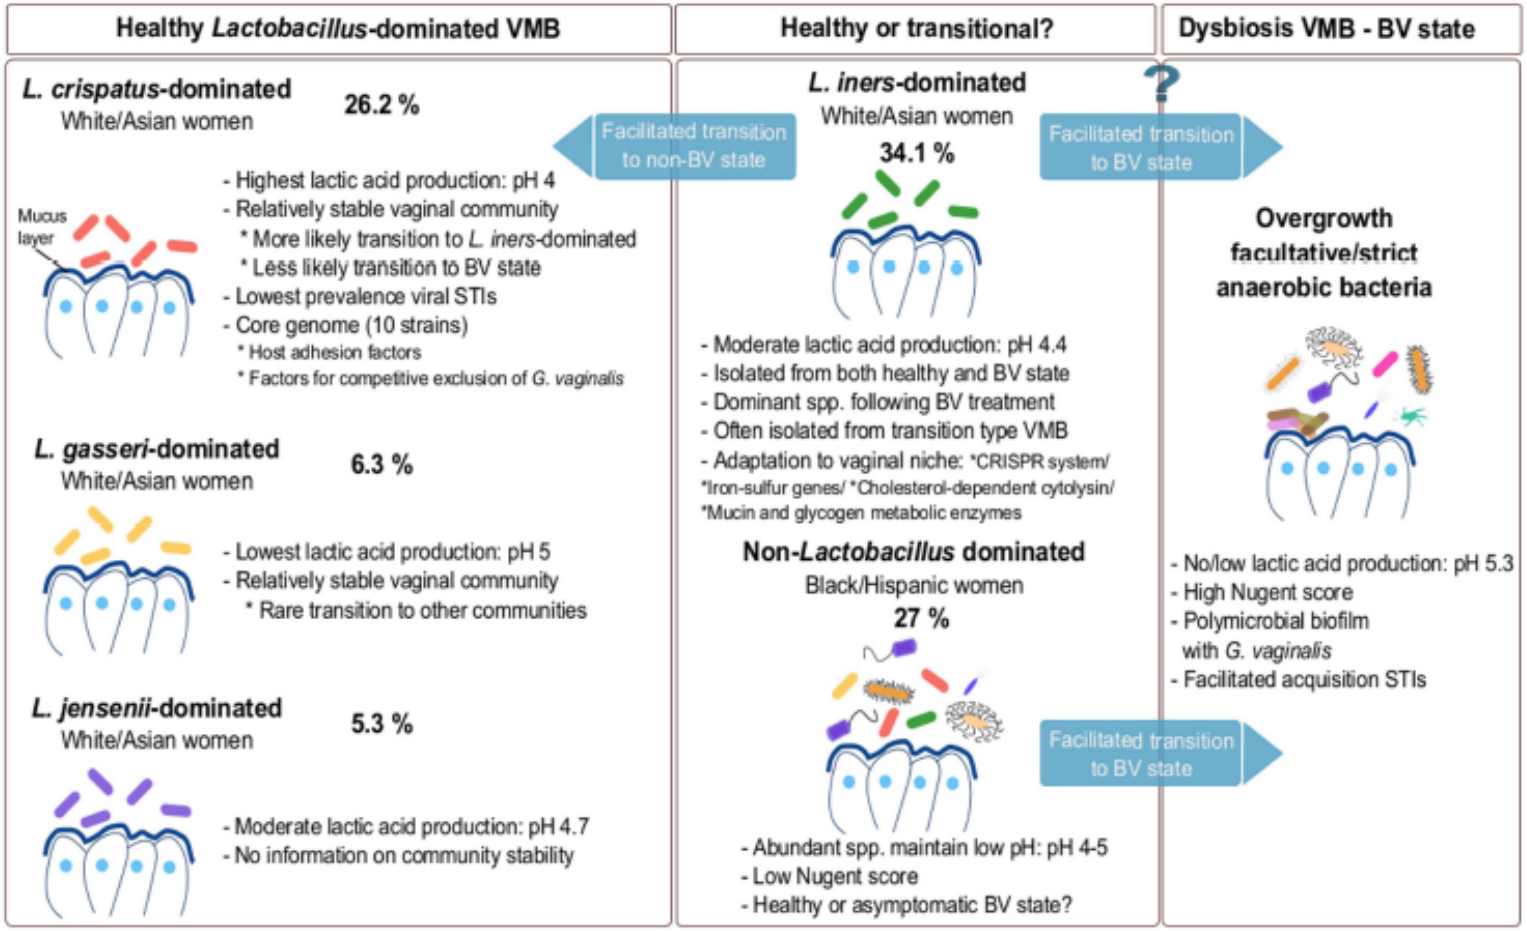

FIGURE 1 | Composition of VMB during healthy and dysbiotic states. The vaginal microbiota in healthy adult premenopausal women can be divided into different community groups. The exact number and type of community groups is still under debate (Verhelst et al., 2005; Ravel et al., 2011; Gajer et al., 2012; Santiago et al., 2012). The most commonly isolated dominating species belong to *L. crispatus*, *L. gasseri*, *L. iners* and *L. jensenii*. The vaginal community group dominated by *L. iners* is also often isolated during menstruation and in the transitional microbiota between healthy and BV state or vice-versa. Because this species is often isolated during BV, *L. iners* may not be able to effectively protect against pathogens. Additionally, a non-*Lactobacillus* dominated VMB is also documented in various healthy individuals (Zhou et al., 2004; Ravel et al., 2011; Santiago et al., 2012). For each compositional state, we have added an example of their abundance based on the study of Ravel et al. (2011). However, these numbers are only exemplary and should be considered with caution, as they clearly depend on the study population (size and characteristics) and they certainly need to be substantiated in further studies.

- The role of *Lactobacillus* is to maintain vaginal homeostasis by producing lactic acid to lower the vaginal pH, the production of hydrogen peroxide, bacteriocins, and other antimicrobial compounds, facilitates the adhesion of *Lactobacilli* to the vaginal epithelial cells and competition for the nutrients in the niche to deter the growth of pathogenic bacteria.

Lactic acid have been shown to affect host immune responses through different mechanisms including :

- eliciting significant increases in the production of the anti-inflammatory mediator i.e. interleukin-1 receptor antagonist (IL-1RA) from vaginal epithelial cells
- inhibiting production of pro-inflammatory mediators i.e. IL-6, IL-8, tumor necrosis factor alpha (TNFα), RANTES (regulated on activation, normal T cell expressed and secreted) and macrophage inflammatory protein-3 alpha (MIP3α)

- releasing transforming growth factor beta (TGF-β) to stimulate antiviral response [20], stimulating the T helper 17 (Th17) T lymphocyte pathway via IL-23 production on exposure to bacterial lipopolysaccharide
- building up cytosolic lactic acid that blocks the production of cyclic adenosine monophosphate (cAMP) leading to increased autophagy in epithelial cells for the degradation of intracellular microbes and upholding homeostasis .

- In contrast, CST-IV is characterized by increased diversity due to polymicrobial colonization with facultative anaerobic bacteria such as *Gardnerella*, *Prevotella*, *Megasphaera*, *Atopobium*, and *Dialister* to the detriment of *Lactobacilli and is associated to a BV*.

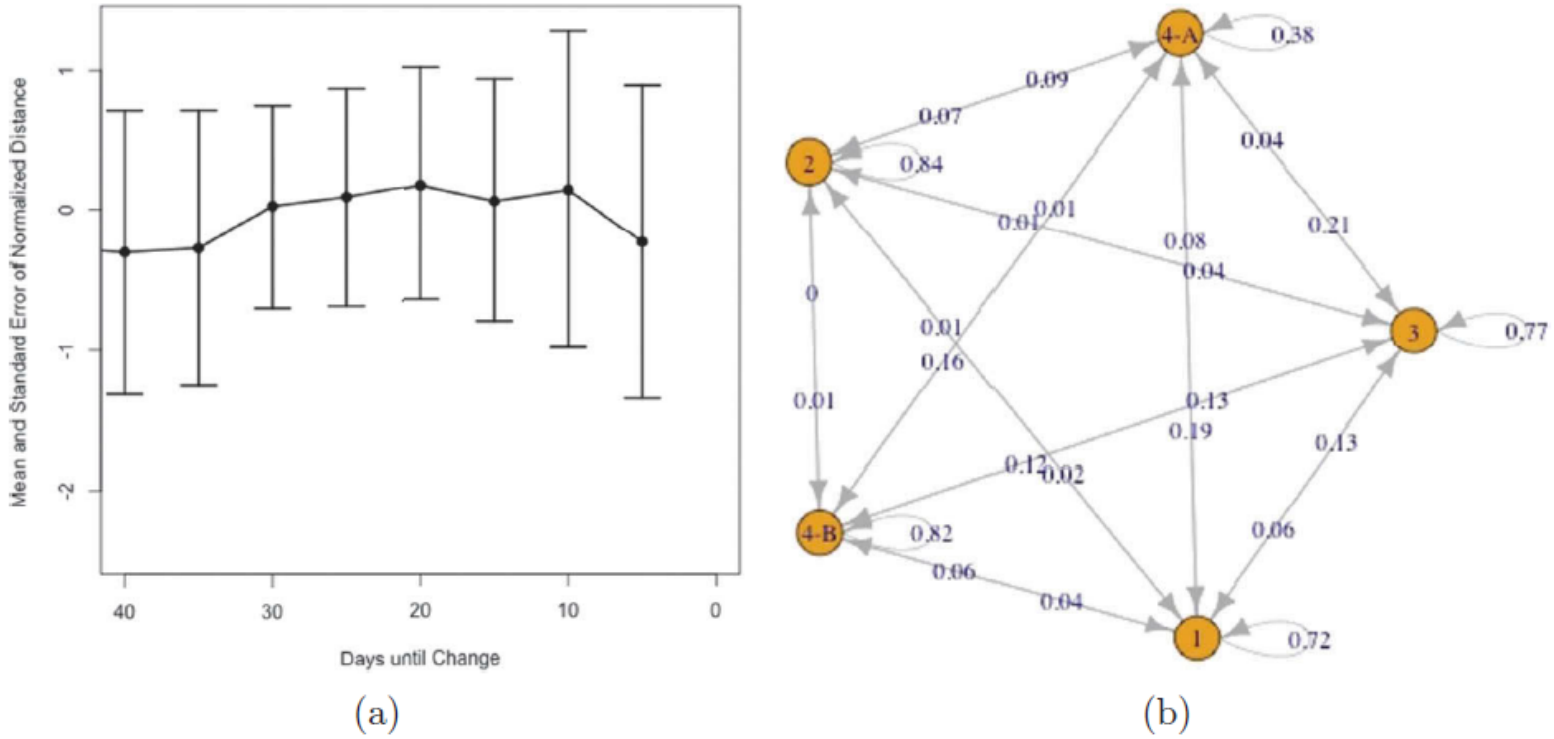
Changes in vaginal community state types reflect major shifts in the microbiome

J. Paul Brooks[a,c], Gregory A. Buck[b,c], Guanhua Chen [d], Liyang Diao[e], David J. Edwards[a], Jennifer M. Fettweis[c], Snehalata Huzurbazar[f], Alexander Rakitin[g], Glen A. Satten[h], Ekaterina Smirnova[f,i], Zeev Waks[j], Michelle L. Wright[k], Chen Yanover[j] and Yi-Hui Zhou[l]

- Shifts between different CSTs occur in women,sometimes involving acquisition of the CST-IV microbiome.
- Healthy subjects persist in a CST for two to three weeks or more on average, while those with evidence of dysbiosis tend to changemore often.
- Changes in CST can be gradual or occur over less than one day. Upcoming CST changes and switches to high risk CSTs can be predicted with high accuracy in certain scenarios



The probability of remaining in a given state over the course of a week is 0.38 (0.22,0.50) for CST 4-A and at least 0.72 (0.61,0.79) for other CSTs (Figure 2(b)).

Effects of combined oral contraceptives, depot medroxyprogesterone acetate and the levonorgestrel-releasing intrauterine system on the vaginal microbiome

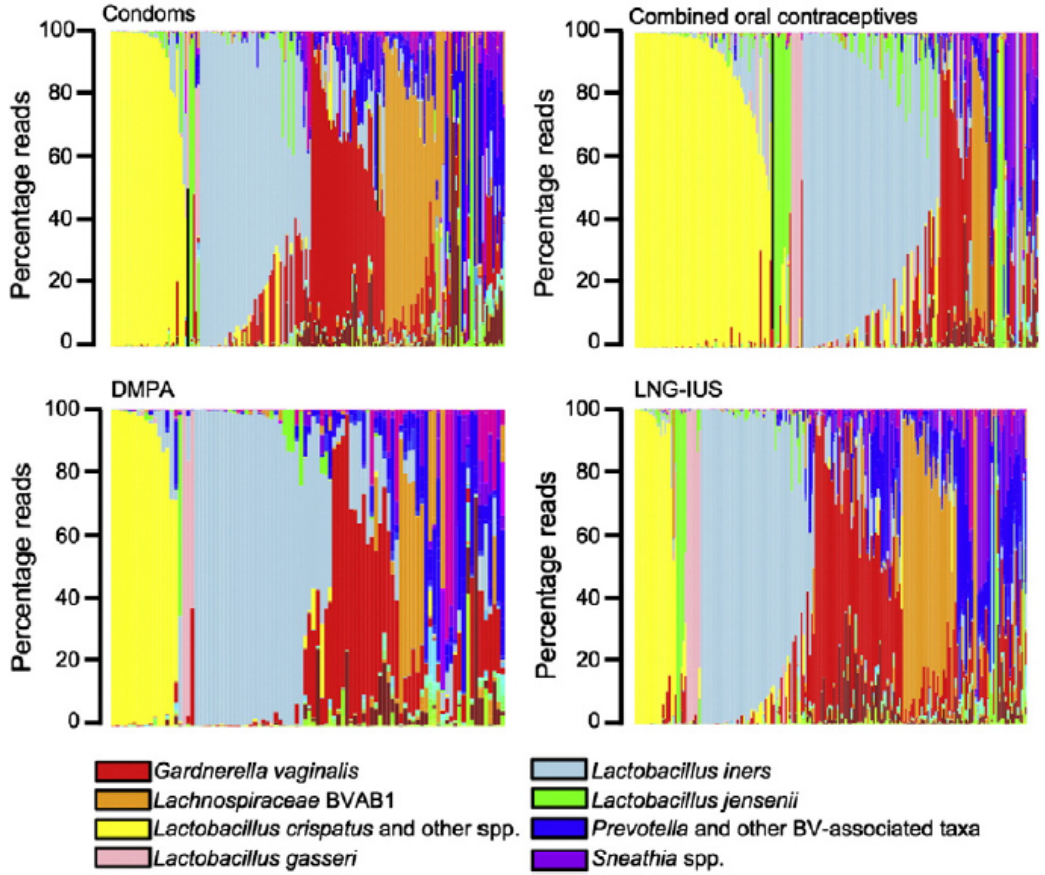

Fig. 1. Microbial community profiles of women using different methods of contraception. Stacked bar plots showing vaginal microbial community profiles from 186 women who reported only using condoms, 206 women who reported only using COCs, 94 women who reported using only DMPA injections and 196 women who reported using only LNG-IUS for contraception. The profiles are grouped by the most abundant species and are ordered by decreasing proportion of the dominant bacterium. An abbreviated color code showing the most abundant taxa is shown. Complete color codes for bacterial taxa appear in Supplementary Data file.

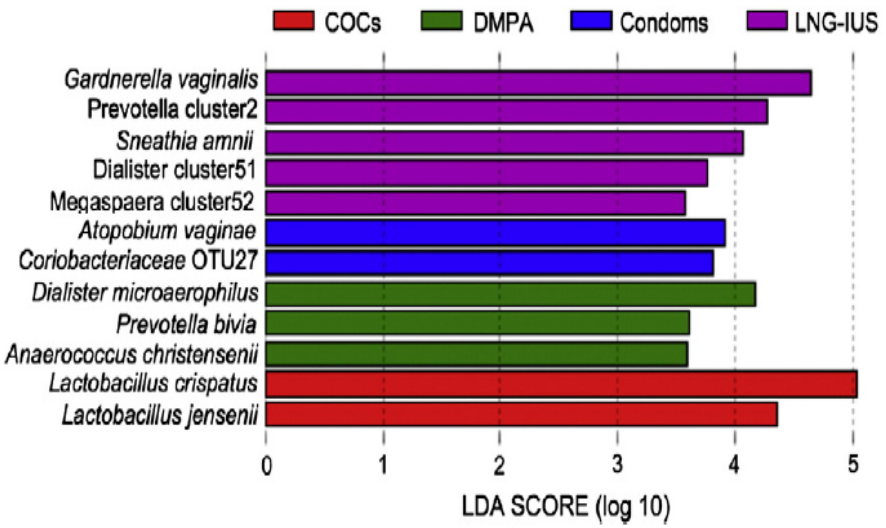

Fig. 2. Association between bacterial taxa and contraceptive method. LEfSe analysis of microbial profiles detected significant associations between the abundance of a number of bacterial taxa and contraceptive method when all methods were compared.

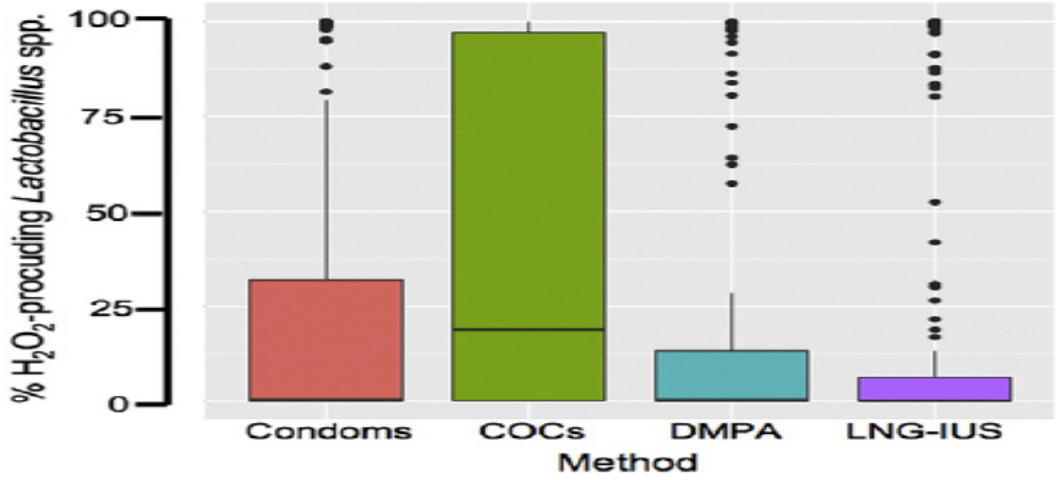

Fig. 4. Relationship between the percentage of H_2O_2-producing *Lactobacillus* species and contraceptive method. The analysis includes healthy women and women with BV. Subjects were grouped based on self-reported contraceptive method. Within each group, the proportion of H_2O_2-producing *Lactobacillus* species, including *L. crispatus*, *L. gasseri* and *L. jensenii*, was plotted. The boxes indicate the interquartile range, and the horizontal line in each box indicates the median.

- Women using COCs and DMPA, but not LNG-IUS were less likely to be colonized by BV-associated bacteria relative to women who used condoms.
- Women using COCs were more likely to be colonized by beneficial H2O2-producing Lactobacillus species compared with women using condoms, while women using DMPA and LNG-IUS were not.

Temporal Dynamics of the Human Vaginal Microbiota

Pawel Gajer, Rebecca M. Brotman

Science Translational Medicine 02 May 2012:

- Among the endogenous factors known to contribute to microbiome changes are hormonal changes during the menstrual cycle.
- These changes are associated with shifts in vaginal bacterial content, with menses representing the phase in which the microbiome is more diverse, while the oestradiol and progesterone peaks are more bacterially stable times.

Menopause and the vaginal microbiome

- The vaginal flora during infancy is a mixture of aerobic and anaerobic bacterial populations including Prevotella, Enterobacteria, Streptococcus, and Staphylococcus species
- After puberty, the estrogen rise leads to the production and accumulation of glycogen, which is essential for *Lactobacillus* growth and the colonization of the vaginal epithelium and pH starts to decrease ; the dominance of *Lactobacillus* is maintained during the reproductive years

- Finally, after menopause, the proportion of *Lactobacillus* species decreases again due to the drop in endogenous estrogen.
- Interestingly, the *Lactobacillus* content, as well as a low vaginal pH, is maintained in women receiving hormonal replacement therapy during menopause.

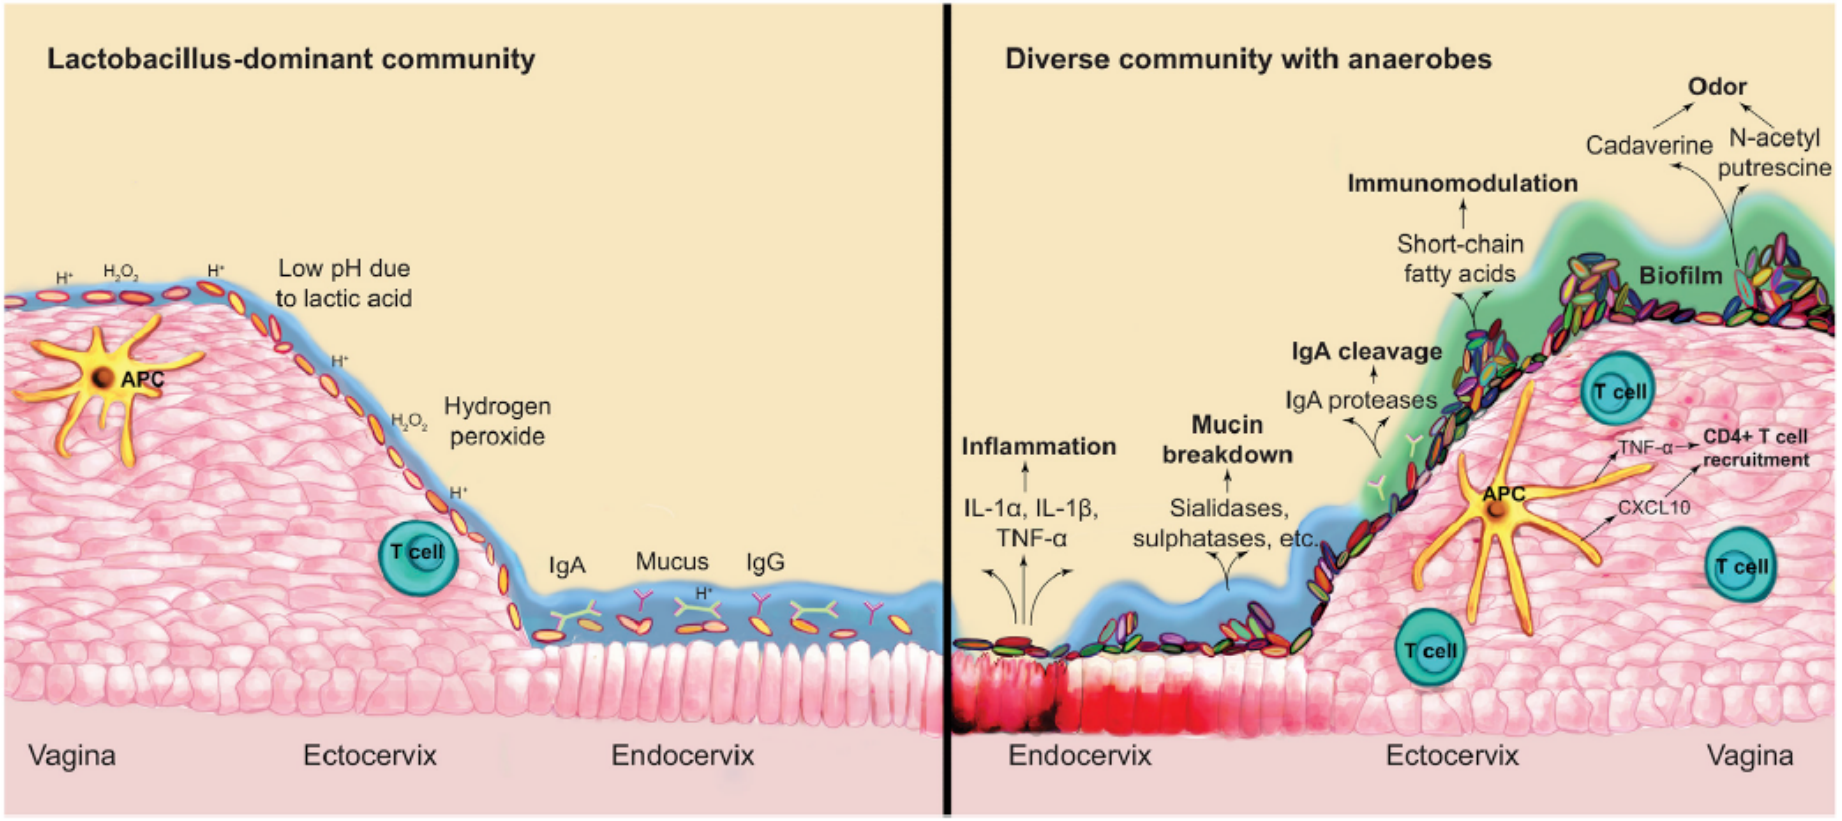

Figure 1. Modulation of the Female Genital Tract Microenvironment by Resident Bacterial Communities

Left: dominance by lactobacilli, particularly *Lactobacillus crispatus*, is associated with a low inflammatory cervicovaginal microenvironment. Lactobacilli protect their niche through the production of lactic acid, which maintains a hostile acidic environment with a pH around 4.0, and hydrogen peroxide, which inhibits the growth of catalase-negative bacteria. The endocervix contributes an innate immune barrier through the maintenance of a thick mucus layer containing IgG, secretory IgA, lactoferrin, lysozyme, and other antibacterial compounds. In this quiescent environment, there are sparse T cells and antigen-presenting cells in the lower reproductive endothelium. Right: in contrast, replacement of lactobacilli with a diverse community of anaerobes can result in a variety of changes to the microenvironment. One of the first signs of bacterial vaginosis is foul-smelling vaginal discharge, which is caused by the bacterial production of chemicals such as cadaverine and N-acetyl putrescine. *Gardnerella*, *Prevotella*, and others can produce sialidases, IgA proteases, and short-chain fatty acids to improve their adherence to epithelial cells, evade antibody-mediated inhibition, and modulate the immune environment, respectively. Epithelial cells and underlying antigen-presenting cells (APCs) respond to *Prevotella*, *Mobiluncus*, and *Sneathia*, for example, by producing pro-inflammatory cytokines including IL-1α, IL-1β, and TNF-α. APCs also produce CXCL10, which can attract additional activated $CD4^+$ T cells to the tissue and may be a key mechanistic link between these diverse communities and increased HIV acquisition risk. These diverse communities become particularly difficult to eradicate after the formation of biofilms.

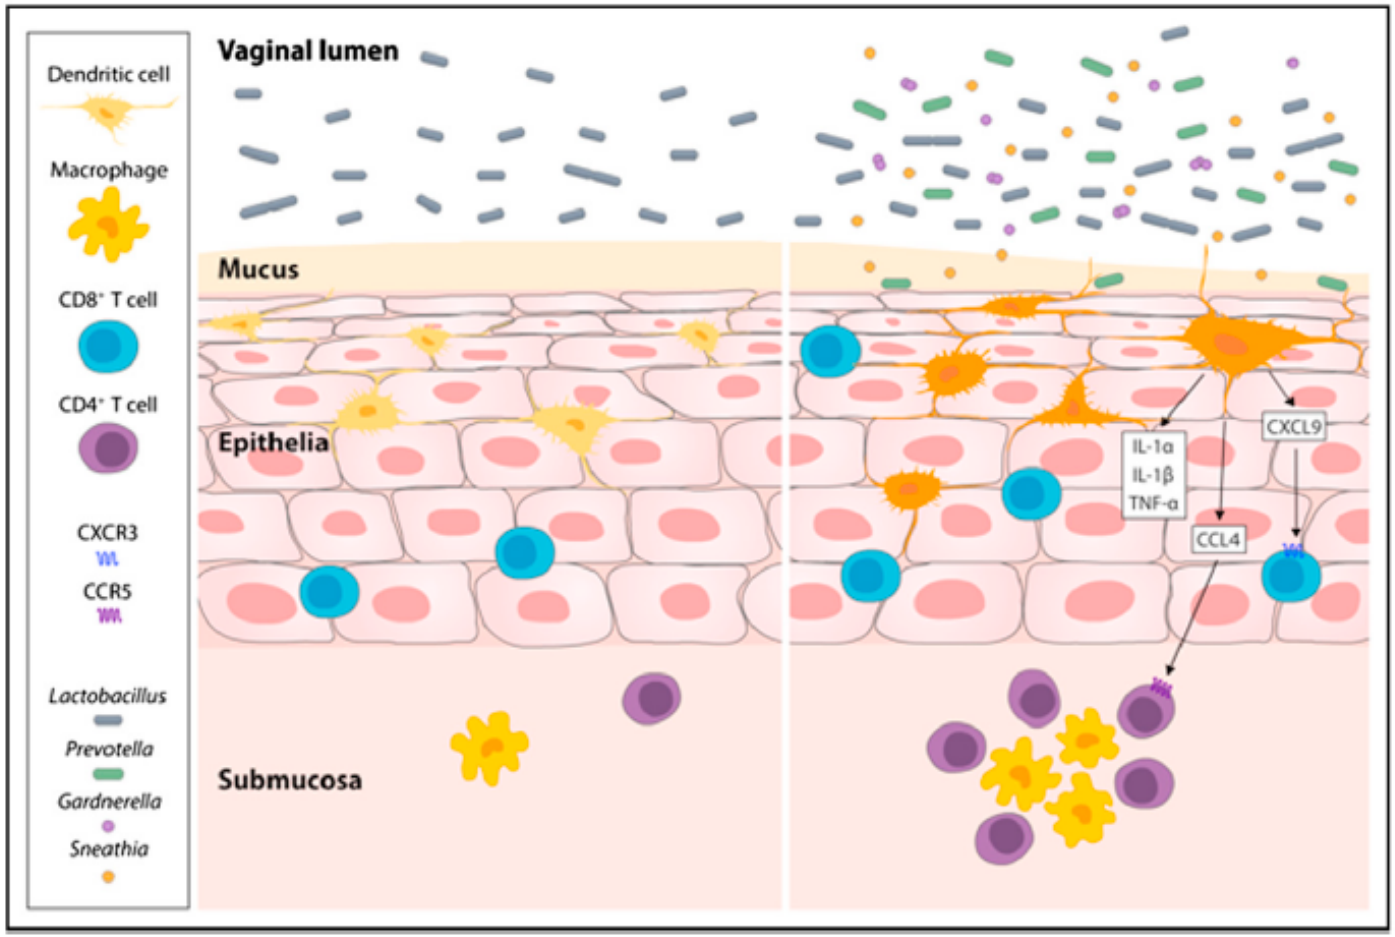

Figure 1. Vaginal Microbial Composition Influences Inflammation and T Cell Abundance

(Left) Low complexity vaginal flora represented by cervicotype CT1 and CT2 are *Lactobacillus* dominant and are not associated with inflammatory cytokine production. (Right) High-diversity vaginal flora, (specifically a cervicotype CT4 enriched for multiple bacterial genera including *Prevotella*, *Sneathia*, and *Gardnerella*) is strongly correlated with increased inflammatory cytokine production by both epithelial cells and activated vaginal APCs. These APCs are potentially directly activated by the vaginal microbiota and secrete both inflammatory cytokines, as well as chemokines resulting in T cell recruitment. Increased numbers of $CCR5^+$ CD4 T cells in hosts with this cervicotype might explain the previously reported link between high-diversity vaginal flora and increased HIV susceptibility. Memory CD4 T cells in the female reproductive tract are often found in close proximity with macrophages in "memory lymphocyte clusters" (Iijima and Iwasaki, 2014). The induction of a localized inflammatory milieu by high-diversity microbiota will likely influence the formation of memory lymphocyte clusters and will be an important consideration in the design of vaccines against STIs, as well as acquisition of HIV-1.

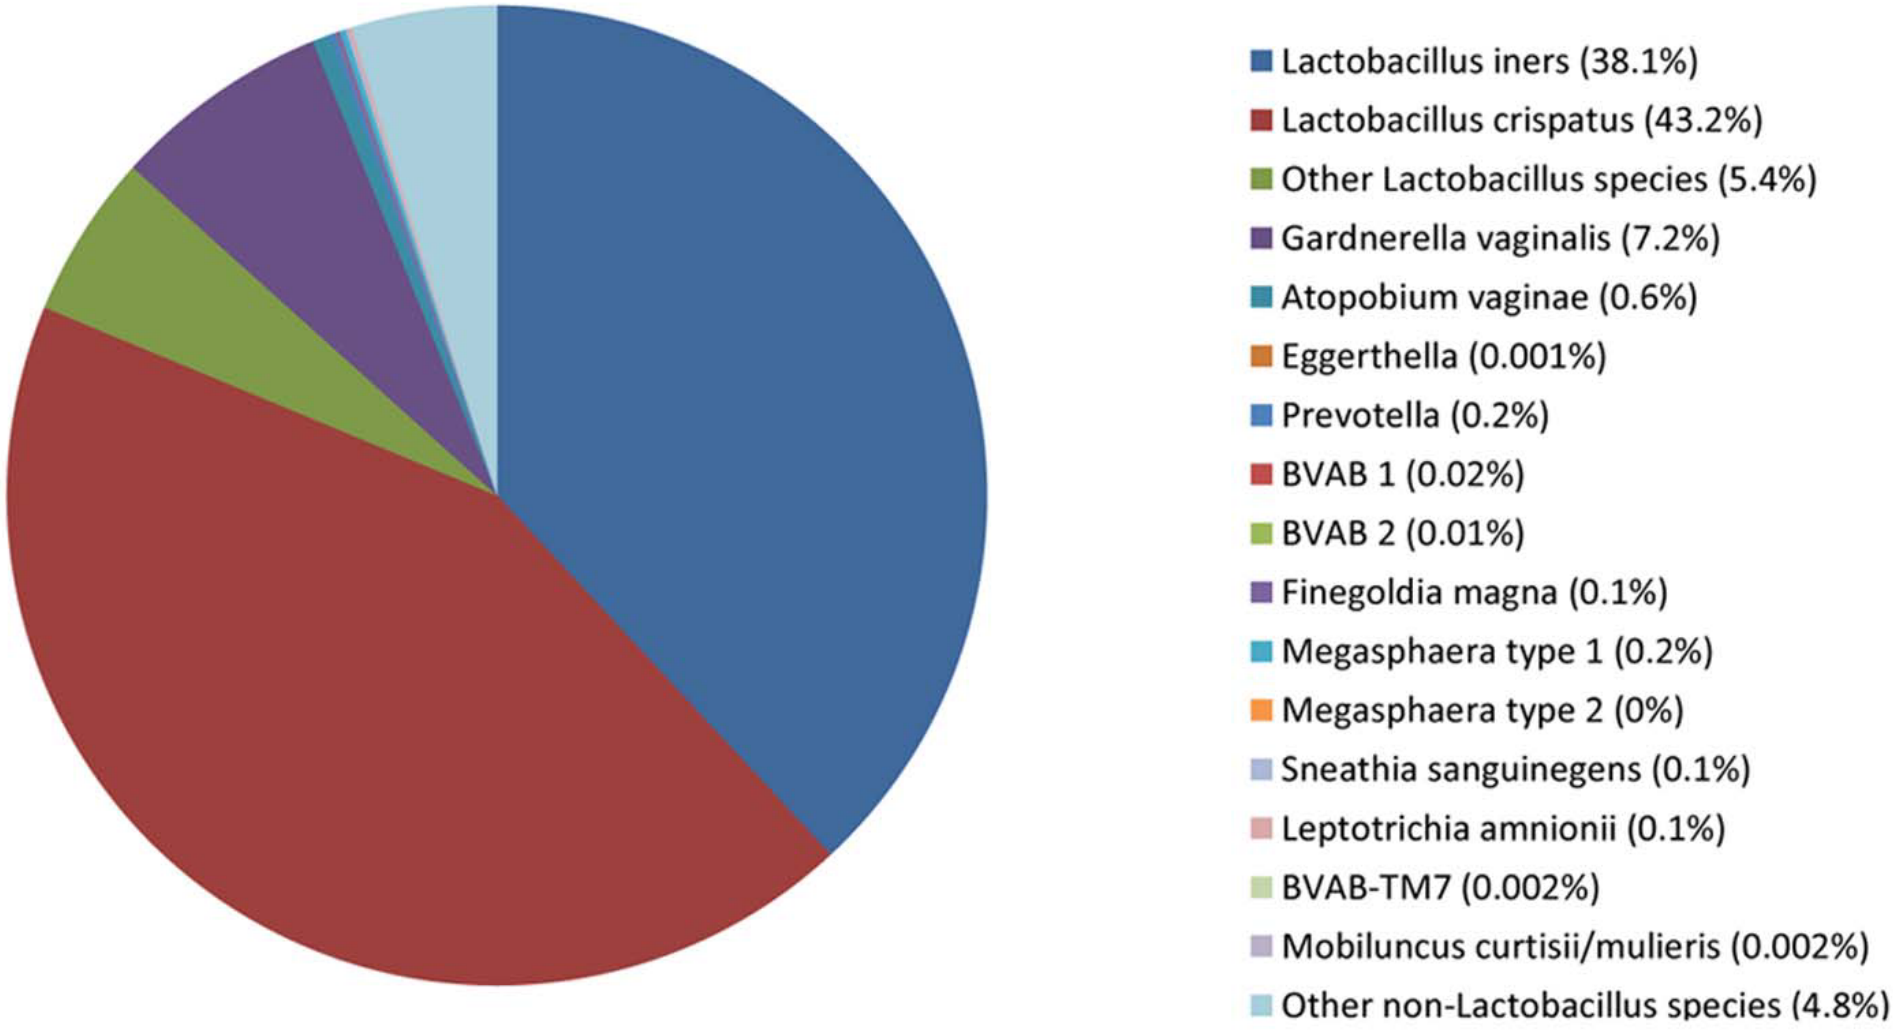
Composition of the Vaginal Microbiota in Women of Reproductive Age – Sensitive and Specific Molecular Diagnosis of Bacterial Vaginosis Is Possible?

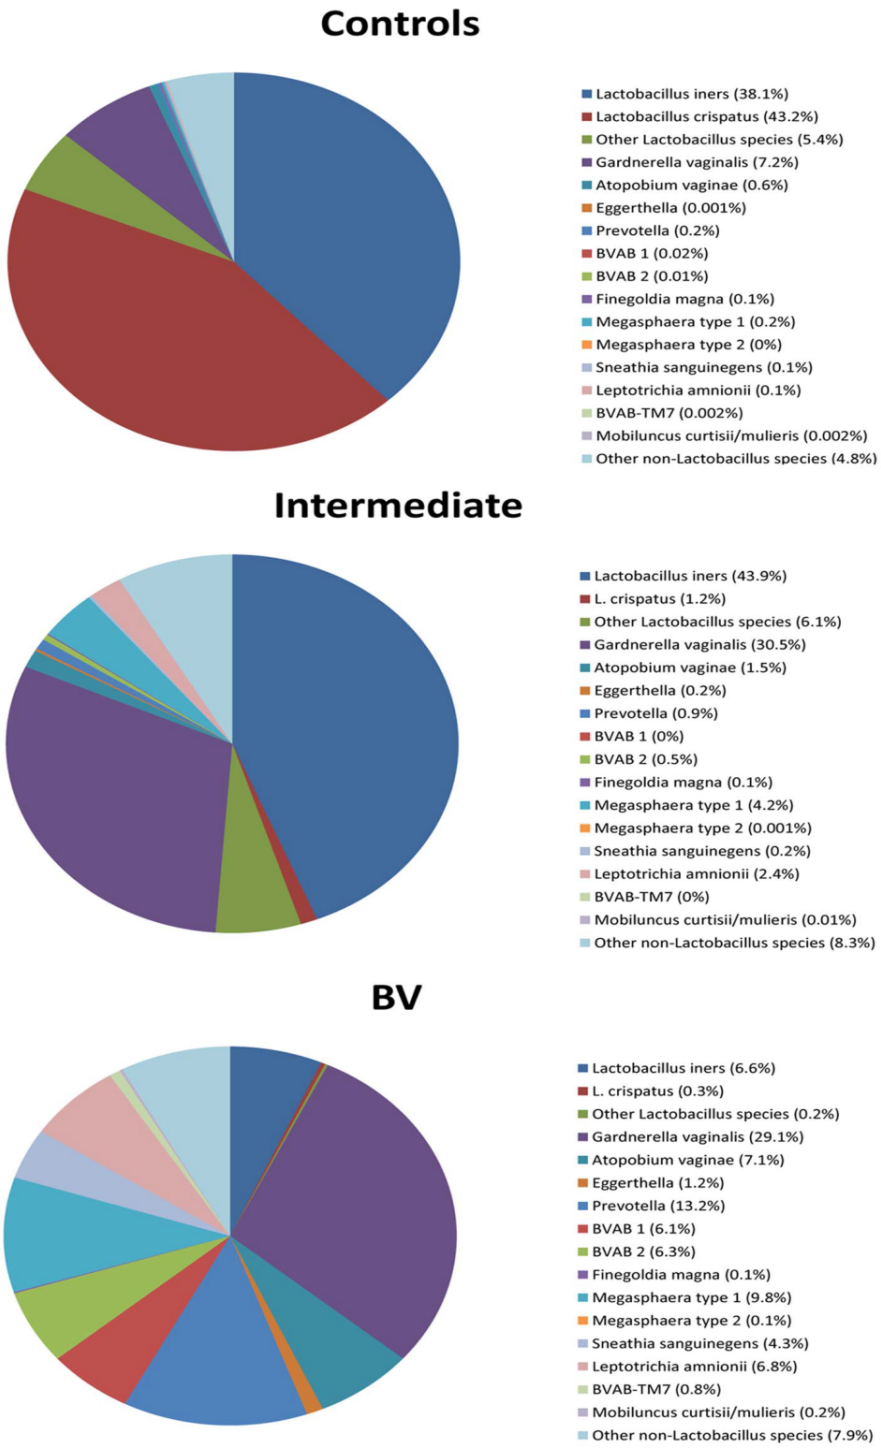
Elena Shipitsyna[1], Annika Roos[2], Raluca Datcu[3], Anders Hallén[4], Hans Fredlund[5], Jørgen S. Jensen[3], Lars Engstrand[2], Magnus Unemo[5]*

- Vaginal samples from 163 women (79 control, 73 BV and 11 intermediate (Lactobacillary grade II flora) cases) were analyzed using 454 pyrosequencing of the hypervariable regions V3–V4 of the 16S rRNA gene and 16 quantitative bacterial species/genus-specific real-time PCR assays.

Controls



Lactobacillus iners (38.1%)
Lactobacillus crispatus (43.2%)
Other Lactobacillus species (5.4%)
Gardnerella vaginalis (7.2%)
Atopobium vaginae (0.6%)
Eggerthella (0.001%)
Prevotella (0.2%)
BVAB 1 (0.02%)
BVAB 2 (0.01%)
Finegoldia magna (0.1%)
Megasphaera type 1 (0.2%)
Megasphaera type 2 (0%)
Sneathia sanguinegens (0.1%)
Leptotrichia amnionii (0.1%)
BVAB-TM7 (0.002%)
Mobiluncus curtisii/mulieris (0.002%)
Other non-Lactobacillus species (4.8%)



- Relative to the healthy women, the BV patients had in their vaginal microbiota significantly higher prevalence, loads and relative abundances of the majority of BV associated bacteria. However, only Gardnerella vaginalis, Atopobium vaginae, Eggerthella, Prevotella, BVAB2 and Megasphaera type 1 detected at or above optimal thresholds were highly predictable for BV, with the best diagnostic accuracy shown for A. vaginae.
- The depletion of Lactobacillus species combined with the presence of either G. vaginalis or A. vaginae at diagnostic levels was a highly accurate BV predictor.

Vaginal microbiota composition and association with prevalent Chlamydia trachomatis infection: a cross-sectional study of young women attending a STI clinic in France.

- Microbiota composition CTS were for 132women
- CST: Lactobacillus Crispatus CST-I 37.1%, L. Iners CST-III 38.6%, and CST-IV 22.0% diversity of anaerobes represented.
- 21/132 women were CT positive.
- Proportions of CT-positive women were higher for samples belonging to CST-III (21.6%) than to CST-I (8.2%) with CST-IV (17.2%).
- 5CST were found in 132 young women from a STI clinic in France. These CSTs were not significantly associated with CT but higher proportions of CT-positive women were found in CST-III and CST-IV, consistent with a previous study in the Netherlands.

Anti-HIV-1 Activity of Lactic Acid in Human Cervicovaginal Fluid

David Tyssen,a Ying-Ying Wang,b

- The *Lactobacillus-dominated vaginal microbiota is associated with a* reduced risk of acquiring and transmitting HIV and other sexually transmitted infections (STIs).
- Lactic acid is a major organic acid metabolite produced by lactobacilli that acidifies the vagina and has been reported to have inhibitory activity *in vitro* against bacterial, protozoan, and viral STIs, including HIV infections.

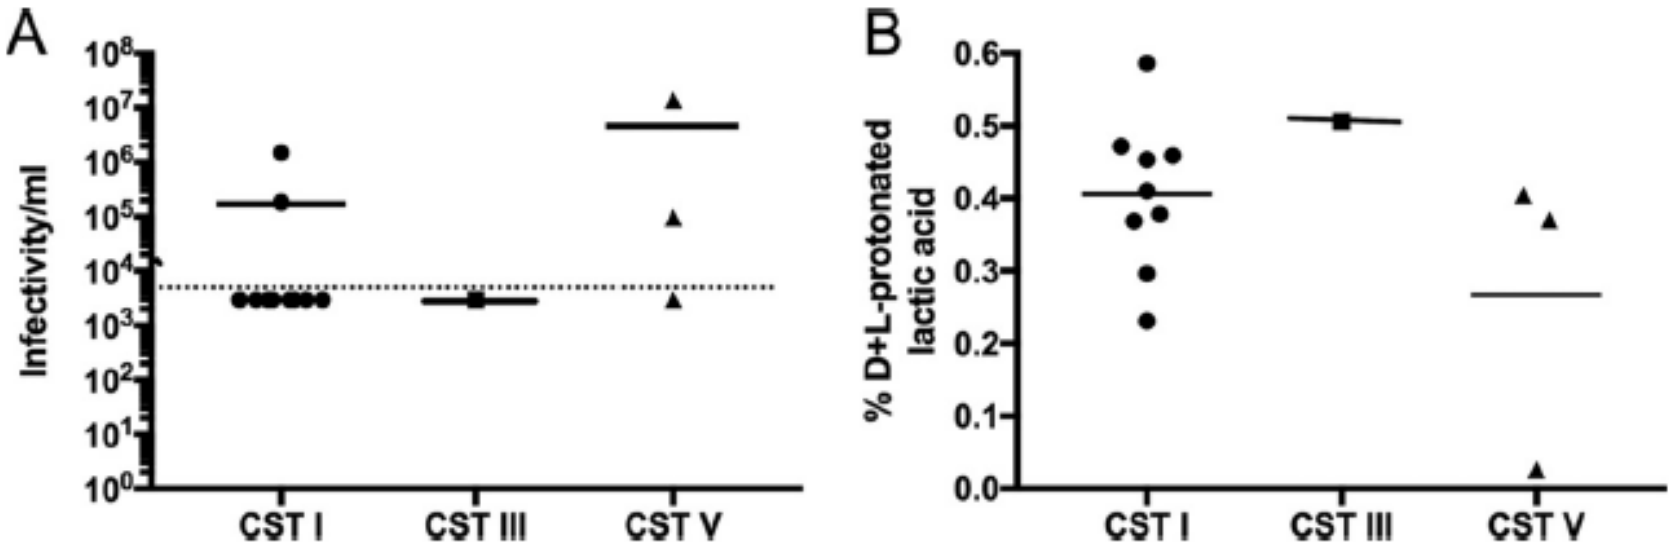

FIG 6 Anti-HIV_{Ba-L} activity and percent D+L-protonated lactic acid (wt/vol) levels of CVF samples with distinct vaginal microbiota dominated by *Lactobacillus* spp. (A) HIV_{Ba-L} infectivity after incubation in CVF samples (HIV_15 to HIV_27) with community state types (CST) dominated by *L. crispatus* (CST I), *L. iners* (CST III), or *L. jensenii* (CST V). Samples represented below the dotted horizontal line were below the detection limit of the infectivity assay. (B) Levels of percent D+L-protonated lactic acid in CVF samples (HIV_15 to HIV_27) categorized as CST (I), CST III, and CST V. Solid horizontal lines represent the means.

- Vaginal colonization with *Lactobacillus crispatus is associated* with reduced risk in women of acquiring HIV .
- HIV-infected women with microbiota dominated by *Lactobacillus spp., particularly L. crispatus, have a lower risk of* HIV genital shedding, which is thought to be associated with reduced HIV transmission to their sexual partners or neonates during vaginal birth

- Women with vaginal microbiota characterized by a high diversity of anaerobes (e.g., *Gardnerella,Prevotella, and Atopobium spp.) and a paucity of vaginal lactobacilli, as exemplified in* cases of bacterial vaginosis (BV) are at higher risk of acquiring HIV from and transmitting HIV to their male partners.

Possiamo classificare i microbioti in :

-***Primari*** : fecale, vaginale, orale, cutaneo e nasale

-***Derivati*** : polmonare, endometriale, vescicale, mammario, intestinale fetale

I microbioti sono interconnessi e le interconnessioni sono strutturate :

- all'interno dell'ospite
- tra ospiti
- con l'ambiente circostante (terreno , atmosfera , cibo e animali)

MICROBIOTI

Consorzi microbici (batterici)

- The upper reproductive tract is not sterile.
- For example, an active uterine microbiome has been characterized in healthy reproductive-age women, but bacteria have also been found to inhabit the fallopian tubes and the ovaries,with *Lactobacillus* the most abundant genus throughout the female reproductive tract.

Subclinical alteration of the cervical–vaginal microbiome in women with idiopathic infertility

Our results suggest that, in the Idiopathic, after a leading alteration caused by a decrease of *L. crispatus* and *L. iners*, and an increase of *L. gasseri*, a synergic action of different anaerobic bacteria, including *Atopobium*, *Prevotella*, *Veillonella*, *Ureaplasma*, and *Escherichia* (Biagi et al., 2009), rather than a predominant species, is involved in the pathogenesis of idiopathic infertility. The drop of some spp. of *Lactobacilli* corresponds to a decrease in acid lactic production and the metabolic byproducts of the anaerobic bacteria lead to an increase of normal vaginal pH (pH > 4.5), favoring a more hospitable niche for opportunistic pathogens.

- The vagina lmicrobiome undergoes significant changes during pregnancy, including a significant decrease in overalldiversity, increased stability (the community composition changes overtime),and enrichment with *Lactobacillus species (Aagaard et al., 2012).*
- *These correlate with a decrease in the vaginal pH and an increase in vaginal secretions (Prince et al., 2014a).*

- Vaginal microbial compositions were found to differ according to gestational age, while the communities at the later stages of pregnancy resembled those of the non-pregnant state (Aagaard et al., 2012).
- A study characterizing the vaginal microbiota of pregnant and non-pregnant African-Americans reported that during pregnancy, one of the changes is dominance of a single *Lactobacillus species over others(Romero et al., 2014a).*

- Some *Lactobacillus species have bactericidal activities against other species,ensuring their predominance and low variability, which may help in protection against infections during pregnancy(Spurbeck and Arvidson, 2010).*

- The postpartum vaginal microbiome was also characterized by gradual depletion of *Lactobacillus species, increased alpha-diversity, and enrichment of bacteria associated with vaginosis, such as Actinobacteria, in 40% of the subjects at 6 weeks after birth (as opposed to only 2% of the subjects during pregnancy; MacIntyre et al., 2015).*

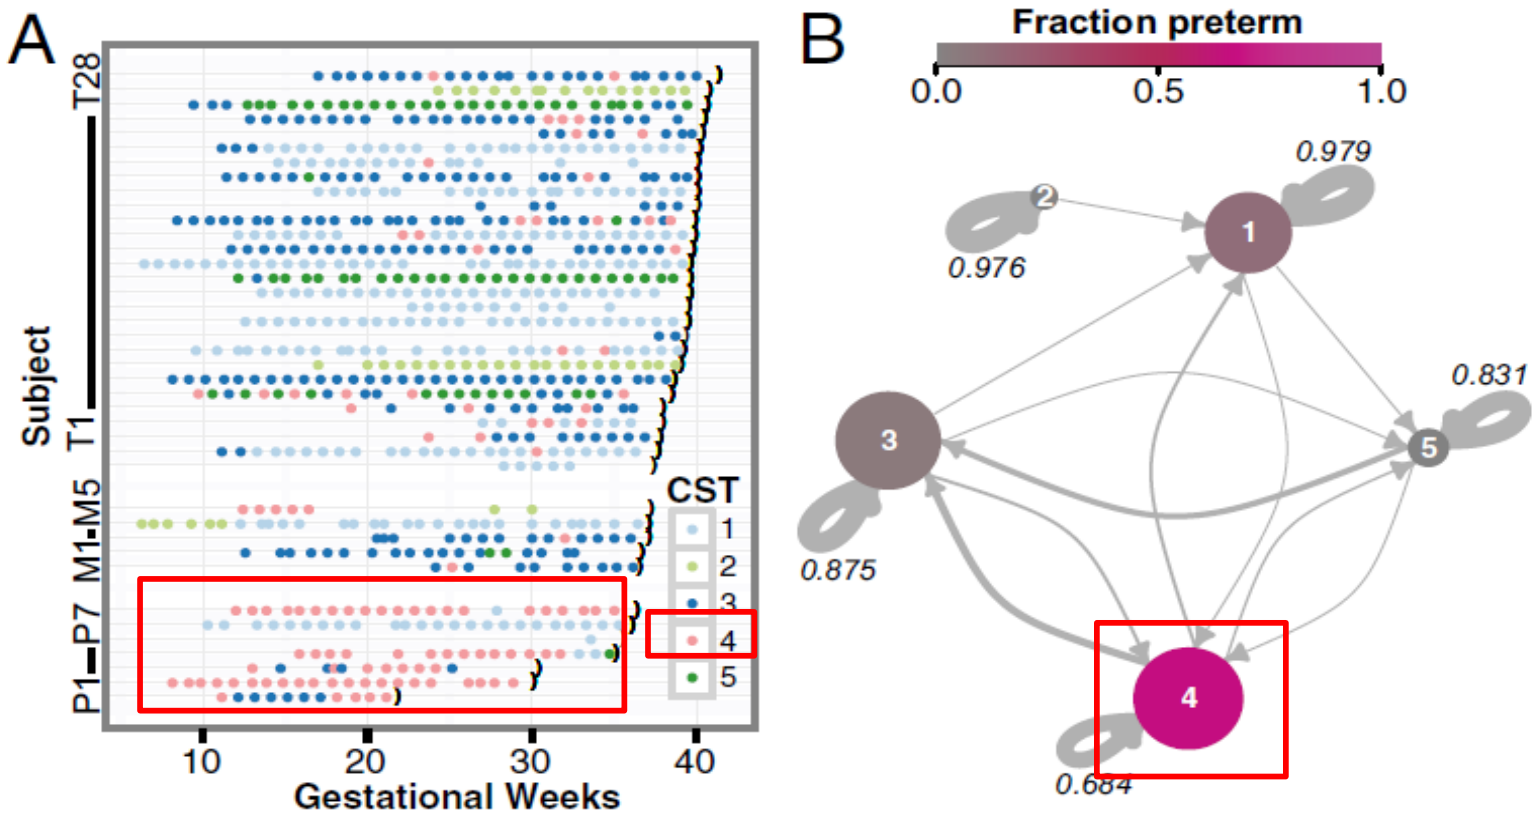
Temporal and spatial variation of the human microbiota during pregnancy

Daniel B. DiGiulio, Benjamin J. Callahan

PNAS | September 1, 2015 | vol. 112 | no. 35

- We conducted a case-control study of 49 pregnant women, 15 of whom delivered preterm. From 40 of these women,we analyzed bacterial taxonomic composition of 3,767 specimens collected prospectively and weekly during gestation and monthly after delivery from the vagina, distal gut, saliva, and tooth/gum.



- Our model indicated that the four Lactobacillus-dominated CSTs (CSTs 1, 2, 3, and 5) were more stable (had higher self-transition probabilities) than the diverse CST (4). This finding is qualitatively similar to the observations of Gajer et al. of CSTs in nonpregnant women (25); however, the Lactobacillus-dominated CSTs were more stable in our cohort

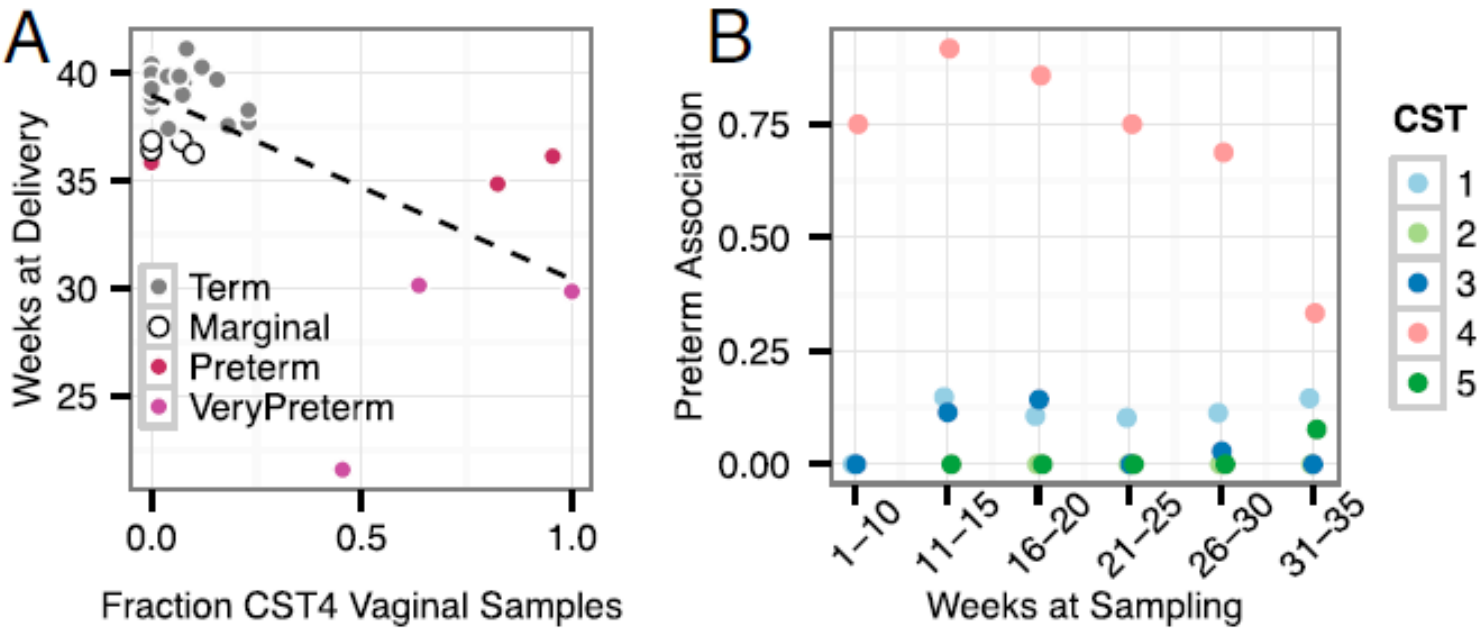


Fig. 4. The high-diversity vaginal CST 4 was associated with earlier deliveries and a higher likelihood of preterm birth in the first group of 40 women. (*A*) Gestational age at delivery is plotted against the fraction of vaginal specimens assigned to the high-diversity CST 4 for the 33 subjects for whom at least 10 vaginal specimens were collected. The dashed line indicates the linear fit. Increased prevalence of the diverse vaginal CST was significantly correlated with earlier delivery ($P = 1.1 \times 10^{-4}$, Pearson; $P = 0.0147$, Spearman). (*B*) The fraction of specimens collected from subjects who delivered preterm is shown by specimen CST and the gestational period during which the specimens were collected. CST 4 specimens collected at any time during pregnancy were associated with a higher proportion of preterm birth.

Diversity and composition of vaginal microbiota of pregnant women at risk for transmitting Group B Streptococcus treated with intrapartum penicillin

Luiz Fernando Wurdig, PLoS One. 2017; 12(2)

- Penicillin administration was associated with an altered vaginal microbial community composition characterized by increased microbial diversity.
- Lactobacillus sp. Contributed only 13.1% of the total community in the women that received penicillinc ompared to 88.1% in the controls.
- Streptococcus sp. Were present in higher abundance in GBS positive woman compared to controls, with 60% of the total vaginal microbiota in severe cases identified as Streptococcus sp.

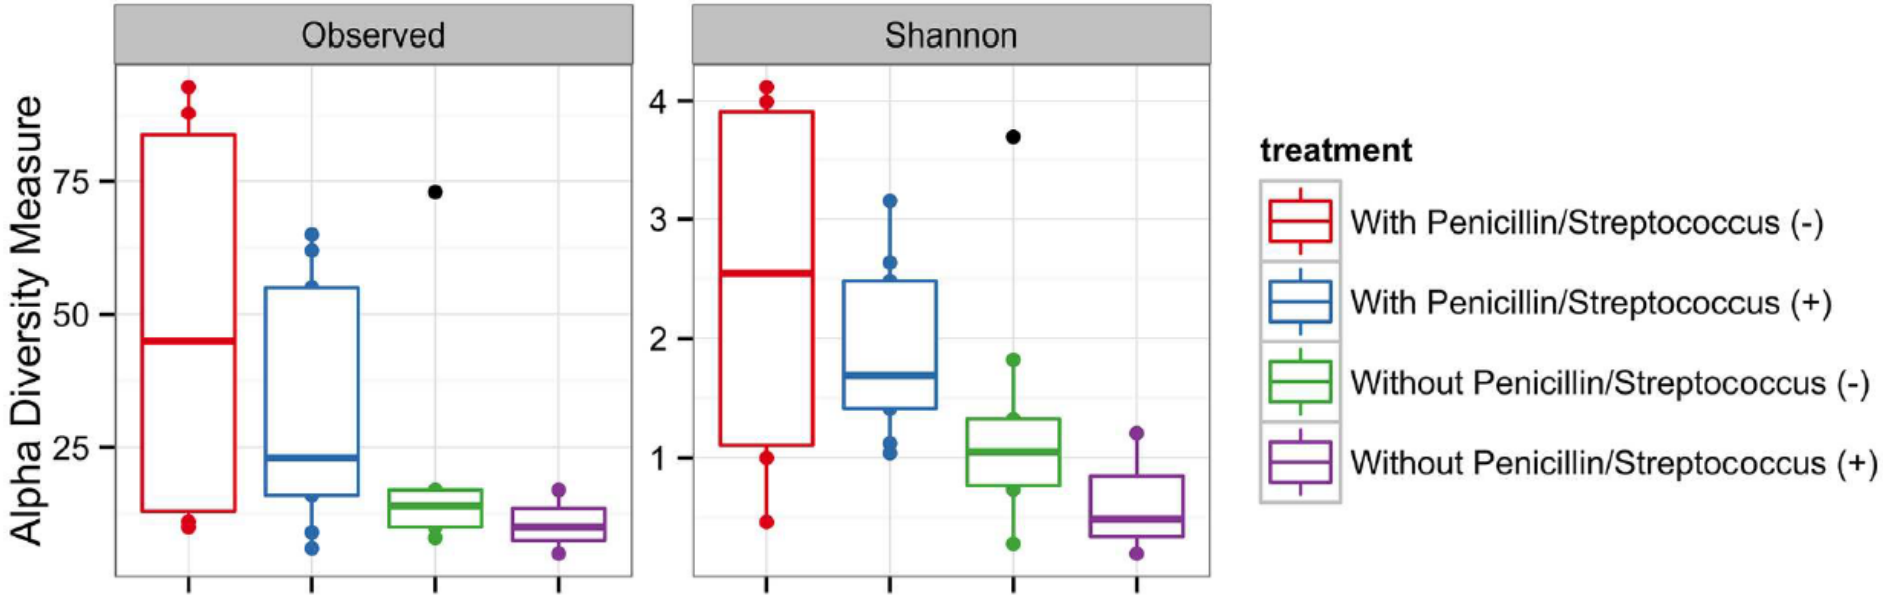

Fig 2. Alpha diversity measurements of vaginal microbial communities from pregnant women under different treatments. The boxes spans the first quartile to the third quartile, the horizontal line inside the boxes represents the median. Lines extending vertically from the boxes indicate variability outside the upper and lower quartiles and the single black circles indicate outliers. After detecting overall differences in beta and alpha diversity among samples, an analysis of the specific taxonomic composition of mothers' vagina was performed in order to identify the microbes responsible for differences among treatments. Significant differences ($p < 0.05$) were observed in the abundance of *Lactobacillus* (Fig 3). *Lactobacillus* spp. was the most abundant genus found in the swab samples from the group of pregnant women without use of penicillin contributing 88.1% and 68.5% with positive and negative *Streptococcus* screening, respectively. In contrast, *Lactobacillus* contributed only 13.1% and 6.0% of the total vaginal microbial community found in the cases with use of penicillin with positive and negative screening for GBS, respectively. *Pseudomonas* was the second most abundant genus among samples contributing up to 6.0% of the total community in those women without use of penicillin. On the other hand, *Pseudomonas* contributed up to 17.5% of the total community in the cases with use of penicillin. Although the average abundance of *Pseudomonas* suggested differences between treatments, such difference was not significant ($p = 0.134$).

- Vaginal communities of healthy pregnant women were dominated by Lactobacillus sp. and contained low diversity, while GroupBStreptococcus positive women receiving intrapartum antibiotic prophylaxis had a modified vaginal microbiota composition with low abundance of Lactobacillus but highermicrobial diversity

- Pregnancy is a remarkable biological process involving simultaneous changes in many physiological systems to support the development of healthy progeny.
- These changes include hormonal changes, weight gain, immune system modulation, and others, which must all be synchronized to preserve the health of both the mother and the offspring (Dunlop et al., 2015).

- While some of the pregnancy- associated hormonal and metabolic changes have been known for decades (Kumar and Magon, 2012)
- The dramatic changes in maternal microbiome composition that take place during gestation have only recently been appreciated.

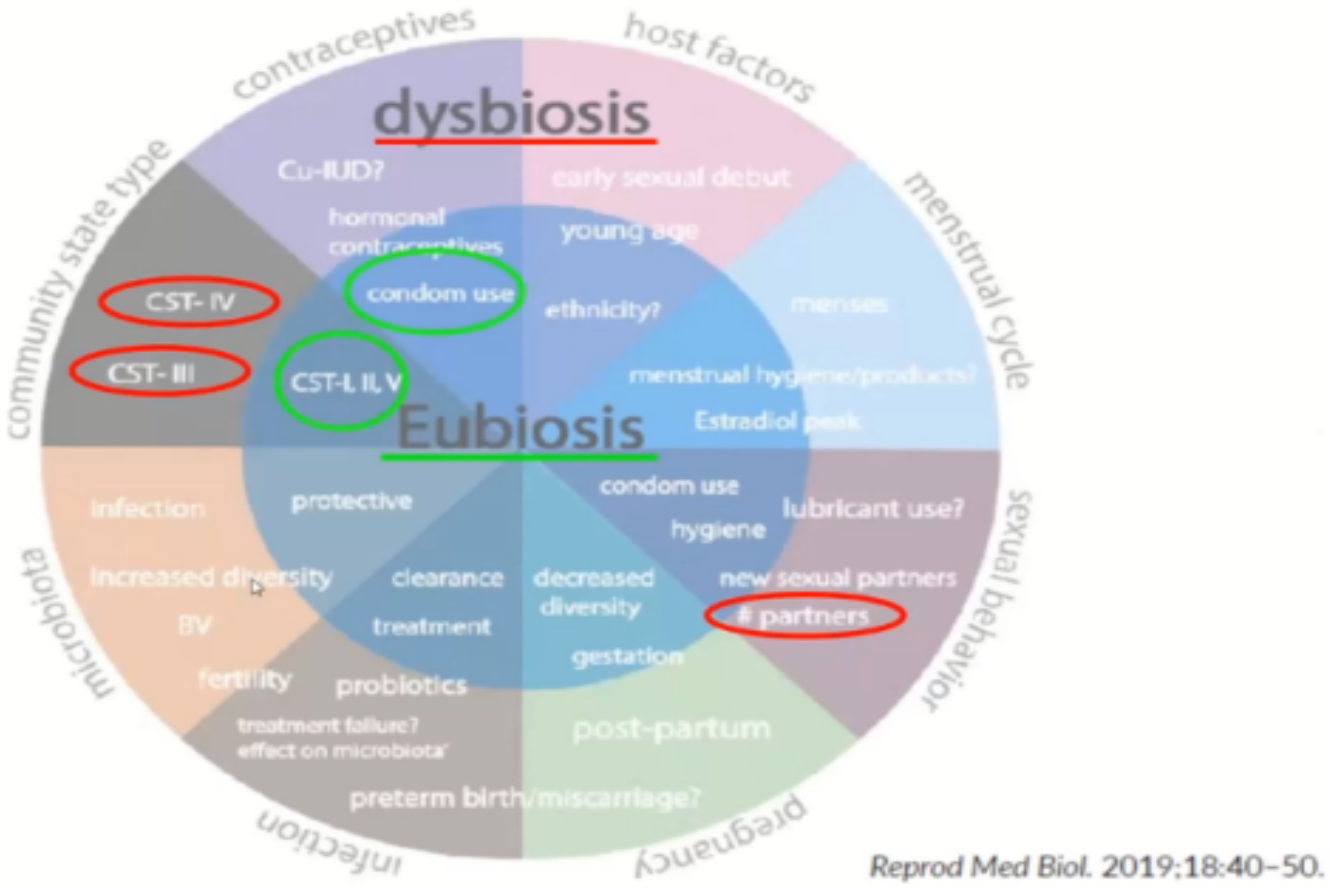
Deciphering the effect of reproductive tract microbiota on human reproduction

Inmaculada Moreno,Carlos Simon



F I G U R E 1 Factors influencing the composition of the cervicovaginal microbiota.

- Healthy pregnancy is characterized by an increase in the bacterial load and profound alterations in the composition of gut microbiota (Collado et al., 2008; Koren et al., 2012).
- In the first trimester of pregnancy, the gut microbial composition is similar to that of healthy, non-pregnant women.

- However,from the first to the third trimester,the gut microbiota composition changes dramatically.
- These changes are characterized by increased abundance of members of the Actinobacteria and Proteobacteria phyla, as well as a reduction in individual richness (alpha diversity; Koren et al., 2012).

- In addition,levels of *Faecalibacterium,* a butyrate-producing bacterium with anti-inflammatory activities, which is depleted in metabolic syndrome patients(Haro et al., 2015), are significantly decreased in the third trimester of pregnancy.

- Between-subject diversity (beta diversity), is increased in the third trimester, coupled with weight gain, insulin insensitivity, and higher levels of fecal cytokines, reflecting inflammation (Koren et al., 2012).

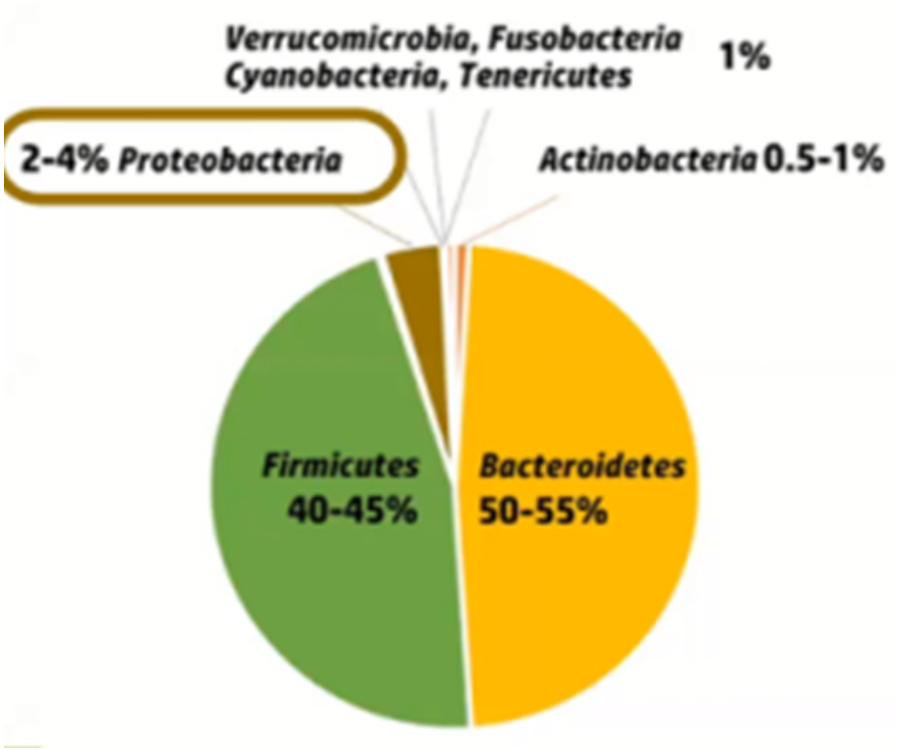
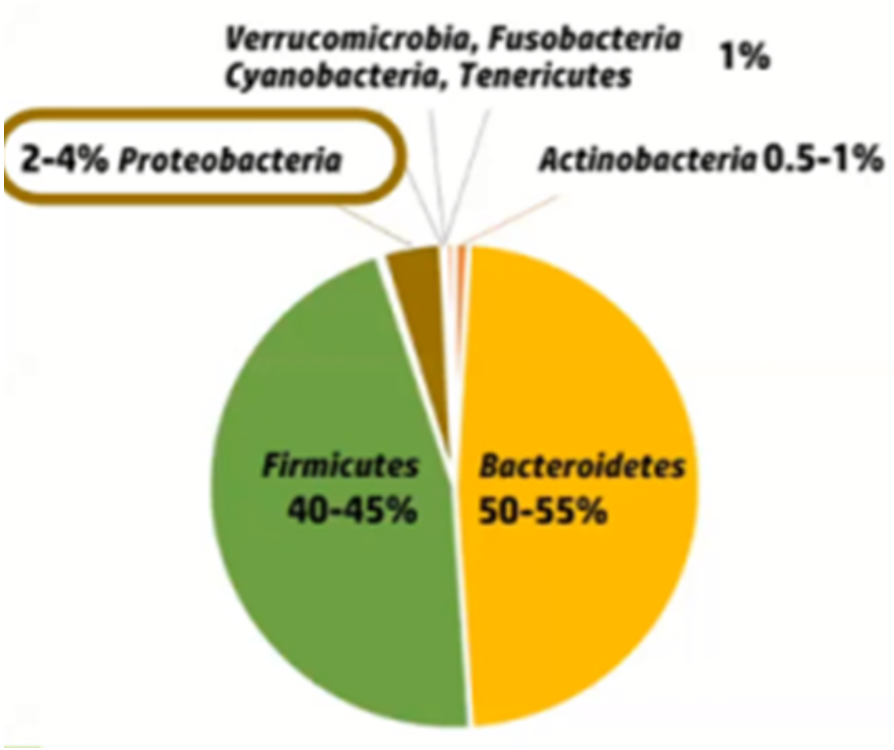
Phylum Proteobacteria

- Gram – pro-infiammatori
- Fisiologicamente abbondanti solo nei neonati e nelle donne in gravidanza , dove sotto la spinta ormonale possono arrivare oltre il 10%



Phylum Actinobacteria

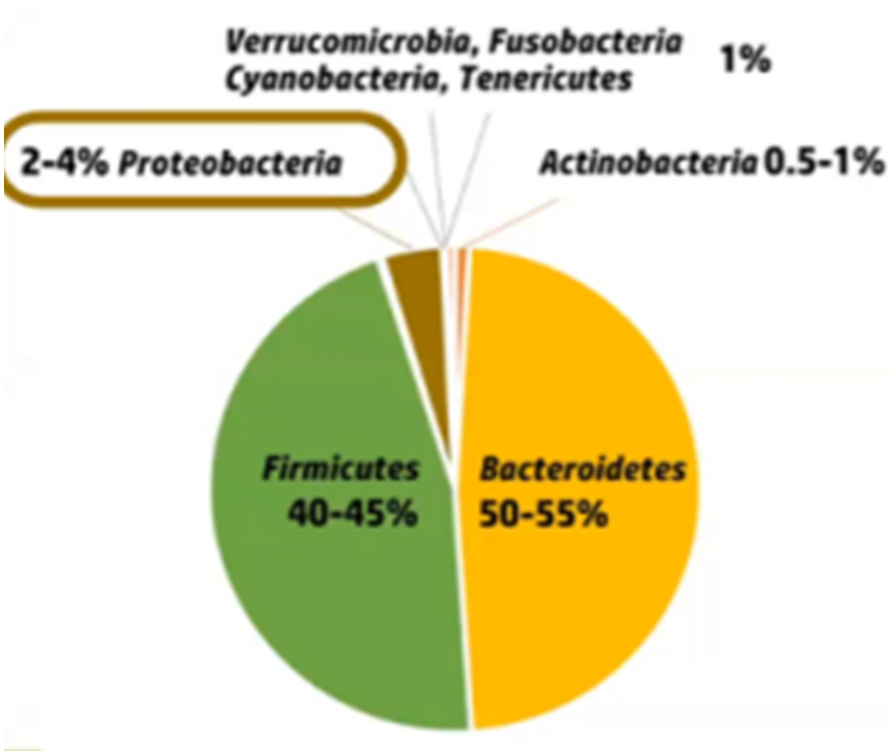
- Gram + anti-infiammatori
- Il genere Bifidobacterium nella fase finale della gravidanza aumenta in modo esponenziale fino al 10/14%
- Nei neonati e nel latte raggiunge il 50%



- In vagina il phylum è rappresentato dai generi Atopobium e Gardnerella , patogeni di origine intestinale
- I Bifidobatteri sono primariamente saccarolitici e quindi metabolizzano nell'adulto i glicani della mucina mentre nei neonati e nei lattanti gli HMO del latte materno

Phylum Verrucomicrobia

- Gram –
- La specie Akkermansia muciniphlia :
- modulo l'ambiente intestinale in senso anti-infiammatorio
- promuove l'integrità della barriera epiteliale attraverso la up regolazione dell'espressione delle proteine del le tight junctions
- Si alimenta del carbonio contenuto nel muco favorendone l'ulteriore ispessimento dello strato
- E' in grado di ridurre i meccanismi infiammatori LPS mediati



- La riduzione del Faecalibacterium Prausnifzil che è un potente batterio butirrato-produttore anti-infiammatorio , si accompagna ad una ulteriore modificazione in eccesso della permeabilità intestinale

- L'infiammazione è uno dei meccanismi cruciali nello sviluppo della insulino resistenza associata a malattie metaboliche quali l'obesità e il diabete tipo 2,
- rilascio di citochine pro-infiammatorie quali il tumor necrosis factor (TNF)-a e la interleuchina-6 (IL-6) ,
- attiva vie di segnale infiammatorie come risultato di una disregolazione cellulare dei pathways omeostatici, come la risposta allo stress del reticolo endoplasmico.

- In many ways, the metabolic changes associated with pregnancy are similar to those that occur in the metabolic syndrome, including weight gain, elevated fasting blood-glucose levels, insulin resistance, glucose intolerance, lowgrade inflammation, and changes in metabolic hormone levels (Fuglsang, 2008; Newbern and Freemark, 2011; Emanuela et al., 2012; Kumar and Magon, 2012).

The gastrointestinal tracts of neonates are colonized by bacteria immediately after birth. It has been discussed that the intestinal microbiota of neonates includes strains transferred from the mothers. Although some studies have indicated possible bacterial transfer from the mother to the newborn, this is the first report confirming the transfer of bifidobacteria at the strain level. Here, we investigated the mother-to-infant transmission of *Bifidobacterium longum* subsp. *longum* by genotyping bacterial isolates from the feces of mothers before delivery and of their infants after delivery. Two hundred seven isolates from 8 pairs of mothers and infants were discriminated by multilocus sequencing typing (MLST) and amplified fragment length polymorphism (AFLP) analysis. By both methods, 11 strains of *B. longum* subsp. *longum* were found to be monophyletic for the feces of the mother and her infant. This finding confirms that these strains were transferred from the intestine of the mother to that of the infant. These strains were found in the first feces (meconium) of the infant and in the feces at days 3, 7, 30, and 90 after birth, indicating that they stably colonize the infant's intestine immediately after birth. The strains isolated from each family did not belong to clusters derived from any of the other families, suggesting that each mother-

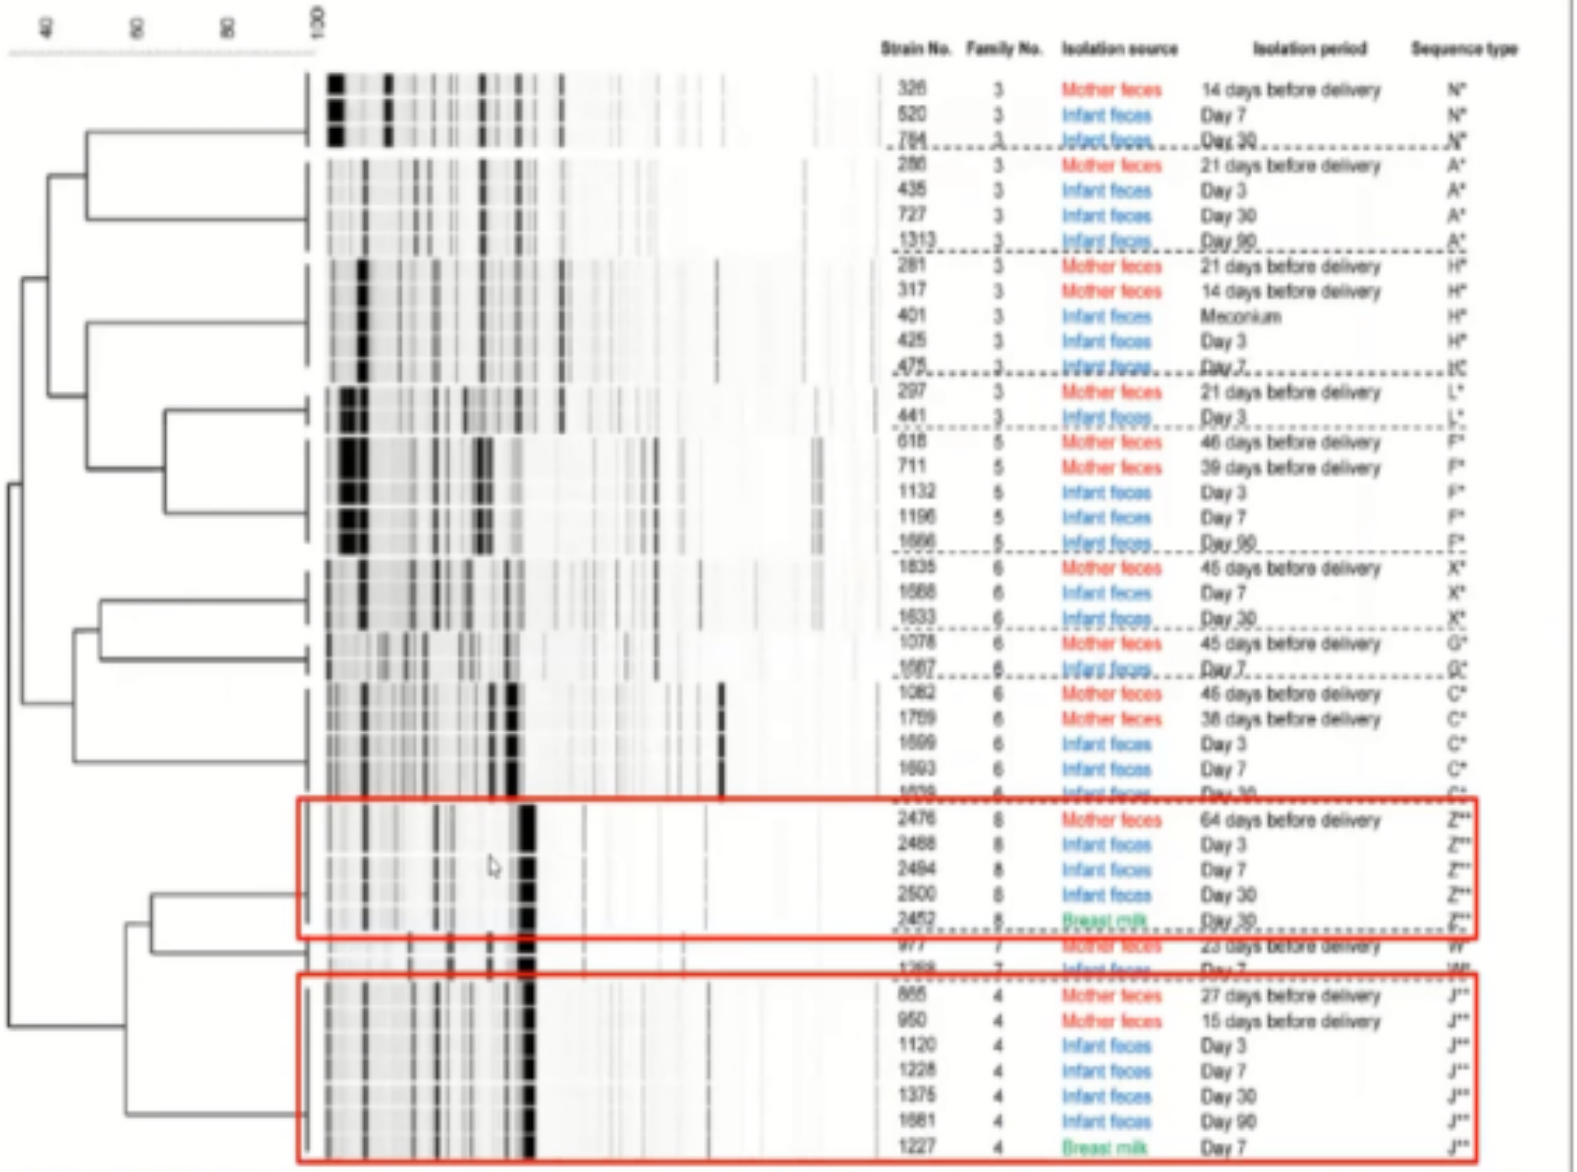

FIG. 2. AFLP profiles of the 11 *B. longum* subsp. *longum* strains found by MLST analysis to be monophyletic between feces from mothers and their infants. Dendrograms were generated with a multiscale setting for comparison and UPGMA for clustering.

WHAT COULD AFFECT A MOTHER'S MICROBIOME DURING PREGNANCY?

- Diet
- Lifestyle
- Exercise
- Stress
- Antibiotics
- Antibacterial practises

- Avoid all perinatal and postnatal environmental factors that may shape the infant microbiota after birth.

- Maternal prenatal psychosocial stress (PNS) and maternal obesity are two important prenatal risk factors that may affects the composition of offspring bacterial microbiota.
- PNS could alter immune development and may increase risk of allergies in childhood

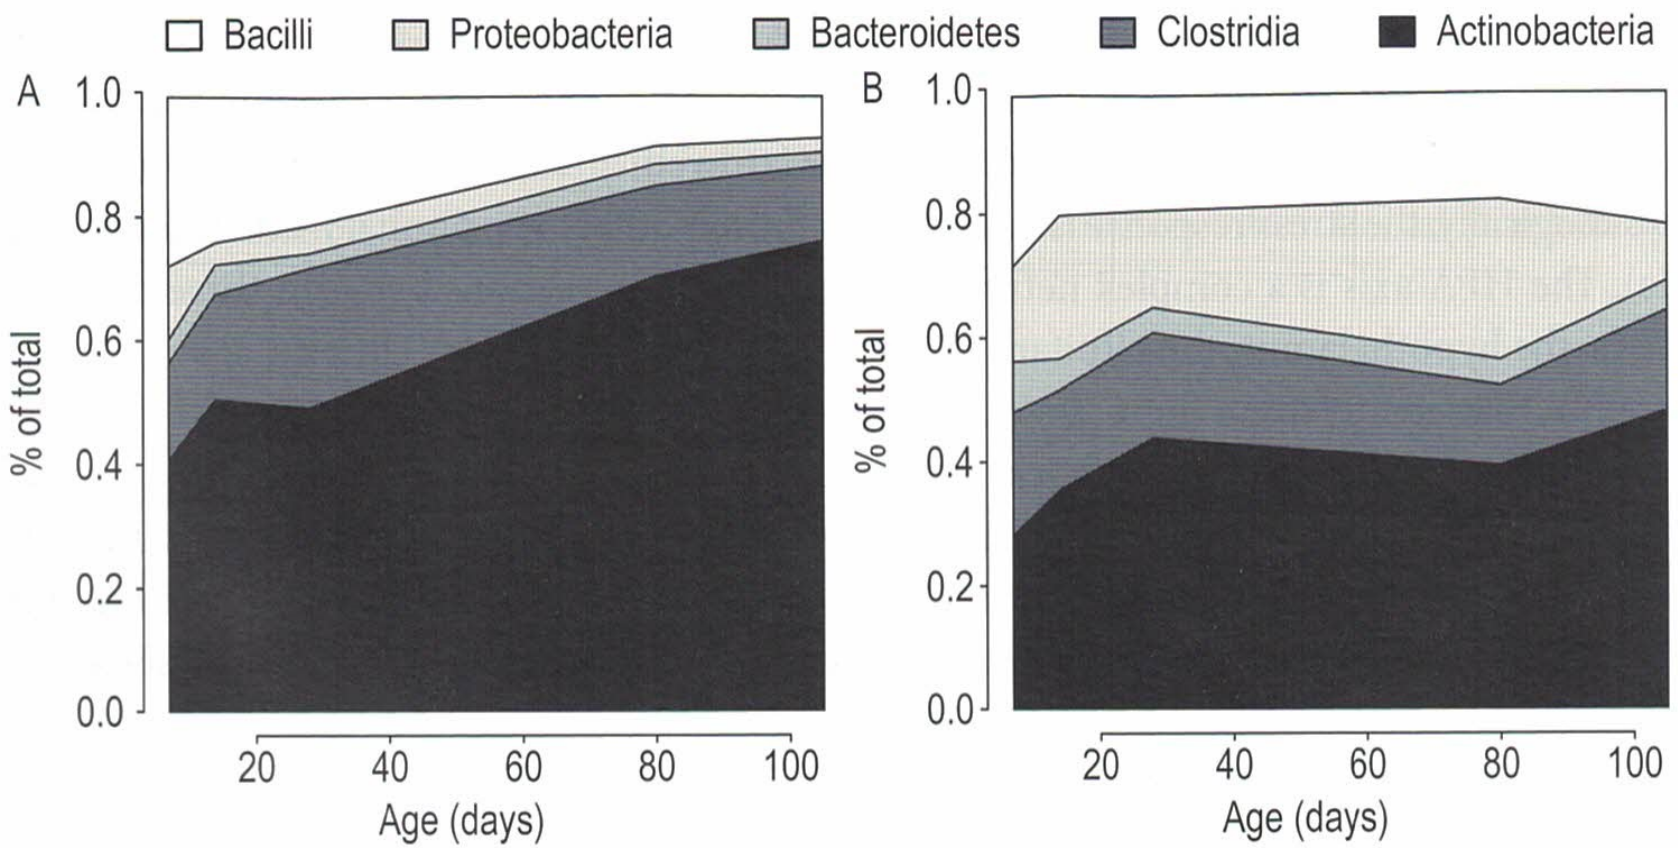

Figure 3.1. The average relative abundance of *Bacilli, Proteobacteria, Bacteroidetes*, *Clostridia* and *Actinobacteria* in infants with (A) exposure to low levels of maternal prenatal reported stress/anxiety as well as low levels of pregnancy cortisol, and (B) exposure to high levels of maternal prenatal reported stress/anxiety as well as high levels of pregnancy cortisol (Zijlmans *et al.*, 2015; Figure is reproduced with permission from Elsevier).

- A clear association exists between maternal obesity during pregnancy and risk of childhood obesity, with increased risk of obesity and diabetes type 2 (DM2) in offspring born to overweight and obese mothers

When transferred to germ-free mice, T3 microbiota induced greater adiposity and insulin insensitivity compared to T1.

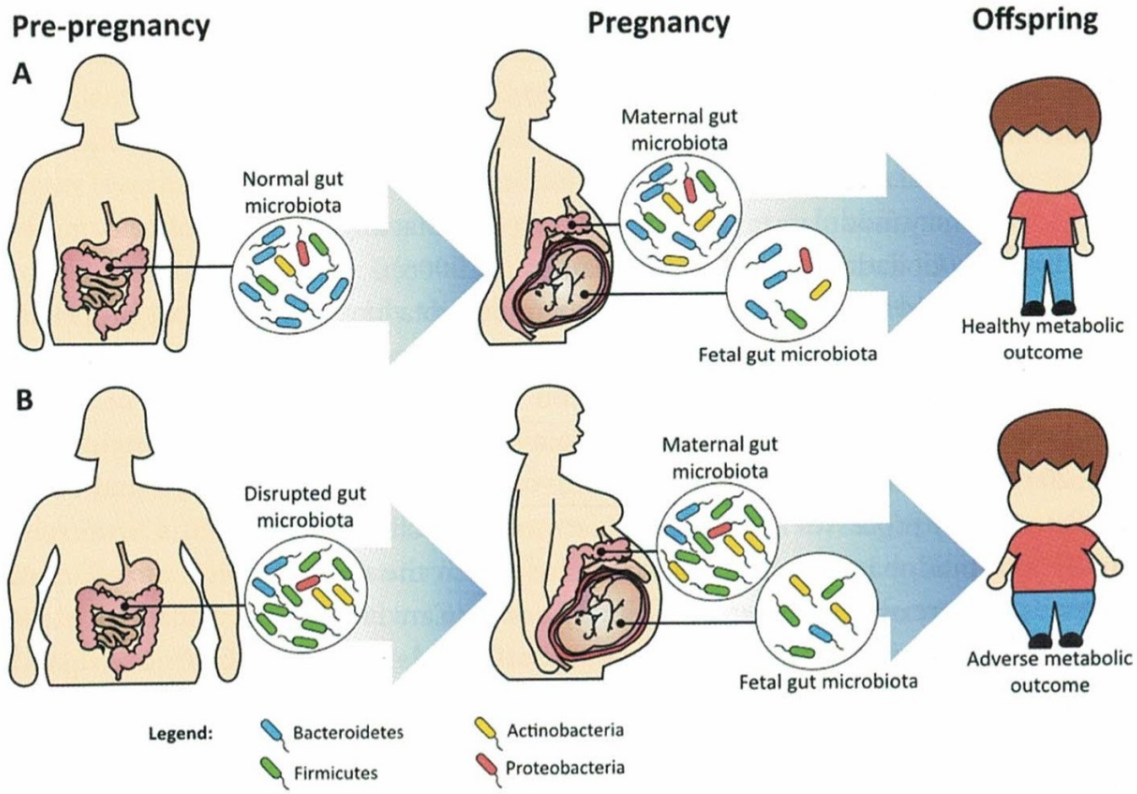

Figure 3.2. A theoretical model supported by empirical studies on microbial changes in the gut during pregnancy in lean versus obese women, and the consequences of maternal obesity on metabolic outcomes in offspring. The gut microbiota changes throughout pregnancy. Lean women, who are thought to possess a healthy microbial composition, maintain the same number of *Firmicutes* (green) and *Proteobacteria* (red) during pregnancy, paired with an increase in *Bacteroidetes* (blue) and *Actinobacteria* (yellow). Obese women with an aberrant gut microbiota, namely increased numbers of *Firmicutes* and *Actinobacteria* and decreased *Bacteroidetes*, display additional unfavourable modifications during pregnancy. *Actinobacteria* and *Firmicutes* further increase, whereas *Proteobacteria* and *Bacteroidetes* stay the same. The abnormal composition confers a disrupted intrauterine environment potentially leading to intestinal dysbiosis in infants with an obese mother, compared to the infants of lean mothers, consequently predisposing these children to adverse metabolic outcomes (Gohir *et al.*, 2015; Ollberding *et al.*, 2015; Scheepers *et al.*, 2015; Serino *et al.*, 2016). (Figure adapted from Gohir *et al.* (2015); reproduced with permission from Elsevier).

- During pregnancy is a period where we really need management of the mother's microbiome. We need to be realising that she's going to pass that on. And what that looks like is really important for what the child will have in early life and the prognosis, then, for health versus disease as that child ages.

- The WHO recommendation that population rates of CS not exceed 15% has been in effect for almost 30 years (WHO, 1985).
- This benchmark remains appropriate to protect the woman and foetus from life-threatening complications, and also to prevent excess maternal and neonatal morbidity and mortality (Althabe and Belizan, 2006; Karlstrom et al., 2013).

- The consequences of CS birth should not be underestimated.
- Women undergoing CS are at greater risk for haemorrhage and uterine rupture (Armson, 2007; Liu et al., 2007), and their newborns have higher rates of respiratory distress and infection (Karlstrom et al., 2013; Magnus et al., 2011).

- Beyond maternal and neonatal risks, a number of risks to child health have been linked to CS birth, including food allergy (Sanchez-Valverde et al., 2009), asthma (Huang et al., 2015) and overweight (Li et al., 2013).

- Emergency and elective caesarean differ by indication, with foetal distress a common feature in the former. As well, many emergency caesareans are performed after a trial of labour, exposing newborns to maternal vaginal microbes.

- In the Canadian Healthy Infant Longitudinal Development (CHILD) cohort, this difference was independent of breastfeeding status (Azad et al., 2016).
- Based on culture methods, a higher percentage of neonates were colonised with Citrobacter freundii and S. aureus one week after emergency than elective CS (or vaginal birth) in the COPSAC2010 cohort

- Klebsiella species were also found to be more abundant in the newborn gut following CS in the GUSTO cohort (Dogra et al., 2015). Finally, Enterococcus becomes more abundant in the infant gut at one or three months following emergency and elective CS (Azad et al., 2016; Stokholm et al., 2016); Stokholm et al. (2016) also reported greater colonisation of the infant hypopharyngeal microbiome with Enterococcus faecalis three months after CS delivery.

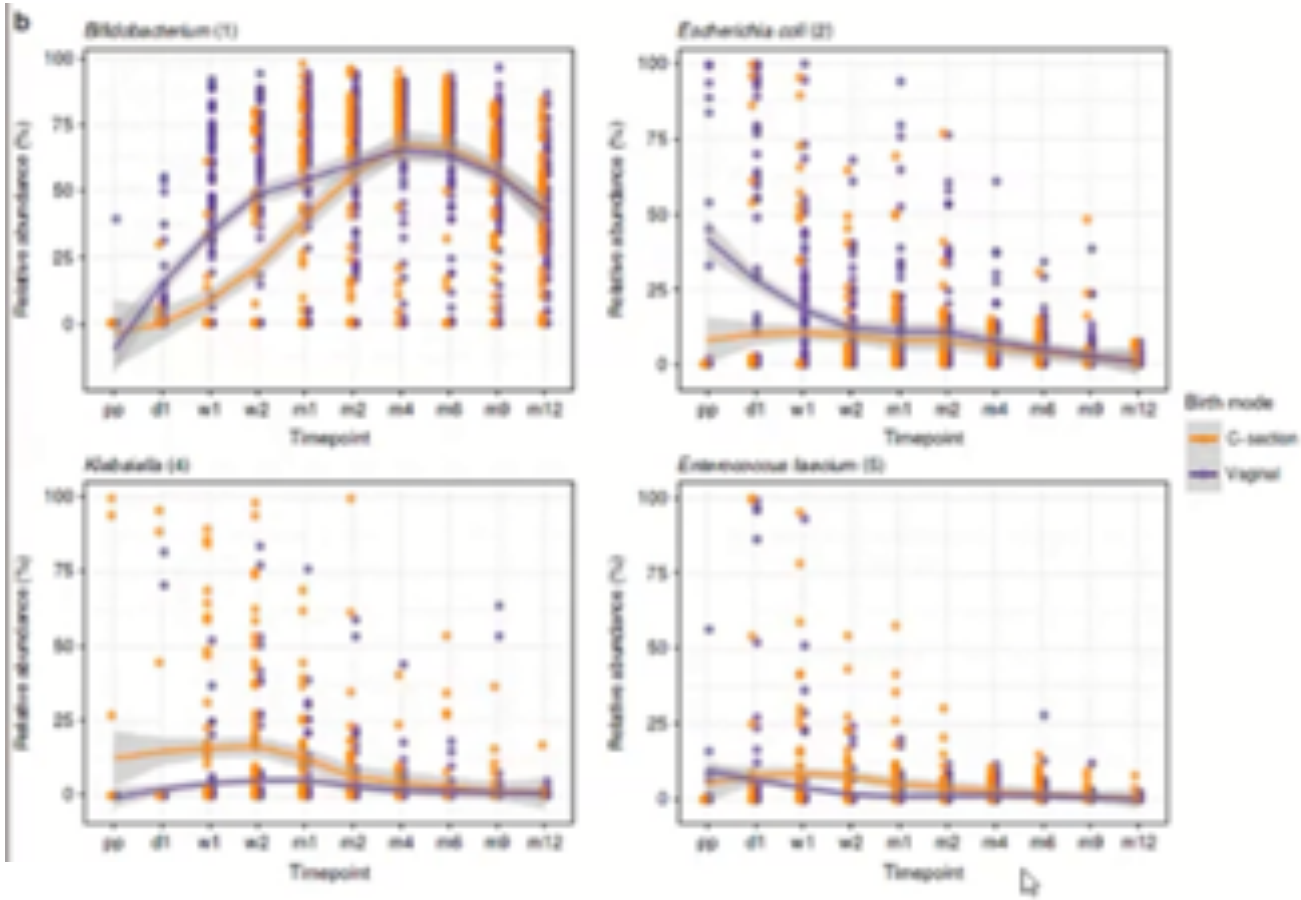
- Concordanza del microbiota fecale del neonato con quello materno rispetto a quello di altre madri molto più alto nel gruppo PS, per l'intero anno di studio, a differenza del neonato nato da TC.
- Differenze nel microbiota tra TC e PS con effetto massimo ad una settimana di vita
- La differenza tra i due gruppi permane a due settimane anche tra gli allattati con formula (eliminazione confondente alimentazione), con maggior presenza di Bifidobatteri e minor presenza di *Klebsiella* e *Staphylococcus* nei nati da PS.
- L'abbondanza di bifidobatteri è associata all'età gestazionale, al parto spontaneo, all'allattamento al seno.
- L'allattamento al seno non compensa completamente la nascita per TC: i nati da TC allattati al seno hanno comunque meno bifidobatteri rispetto ai nati da PS allattati con formula.
- I nati da PS hanno anche più Bacteroides rispetto ai nati da TC.



Bifidobatteri più abbondanti in PS rispetto a TC per i primi 30 giorni, anche quando corretto per il fattore allattamento.
E. coli più abbondante nei neonati PS che nei TC per i primi 85gg
Klebsiella più abbondante nei TC fino al giorno 139
Enterococcus più presente nei TC tra 7 e 35 gg

IL LATTE MATERNO rappresenta un rifornimento continuo di batteri commensali, mutualistici e / o potenzialmente probiotici nell'intestino infantile.

Questi hanno rivelato il predominio di stafilococchi, streptococchi, batteri dell'acido lattico e bifidobatteri in questo fluido biologico e il loro ruolo sulla colonizzazione dell'intestino infantile.

- Alcuni batteri presenti nell'intestino materno potrebbero raggiungere la ghiandola mammaria durante la tarda gravidanza e l'allattamento attraverso un meccanismo che coinvolge i monociti dell'intestino.

Gli oligosaccaridi del latte umano (HMO) possono influenzare ulteriormente la costituzione di un microbioma sano:

- legando i batteri potenzialmente nocivi,
- modulando la risposta immunitaria
- promuovono la crescita di Batteri buoni come i

Bifidobacterium infantis prevenendo così le infezioni

- impedendo l'attaccamento alle cellule ospiti, prevenendo così l'adesione e l'invasione dei patogeni
- effetti antimicrobici diretti su alcuni patogeni
- modulano le risposte delle cellule epiteliali intestinali e agiscono da modulatori immunitari
- alterano l'ambiente del villo intestinale, riducendo la crescita cellulare e inducendo differenziazione e apoptosi
- alterano le risposte immunitarie spostando le risposte delle cellule T ad una produzione di citochine Th1 / Th2 bilanci*ata*

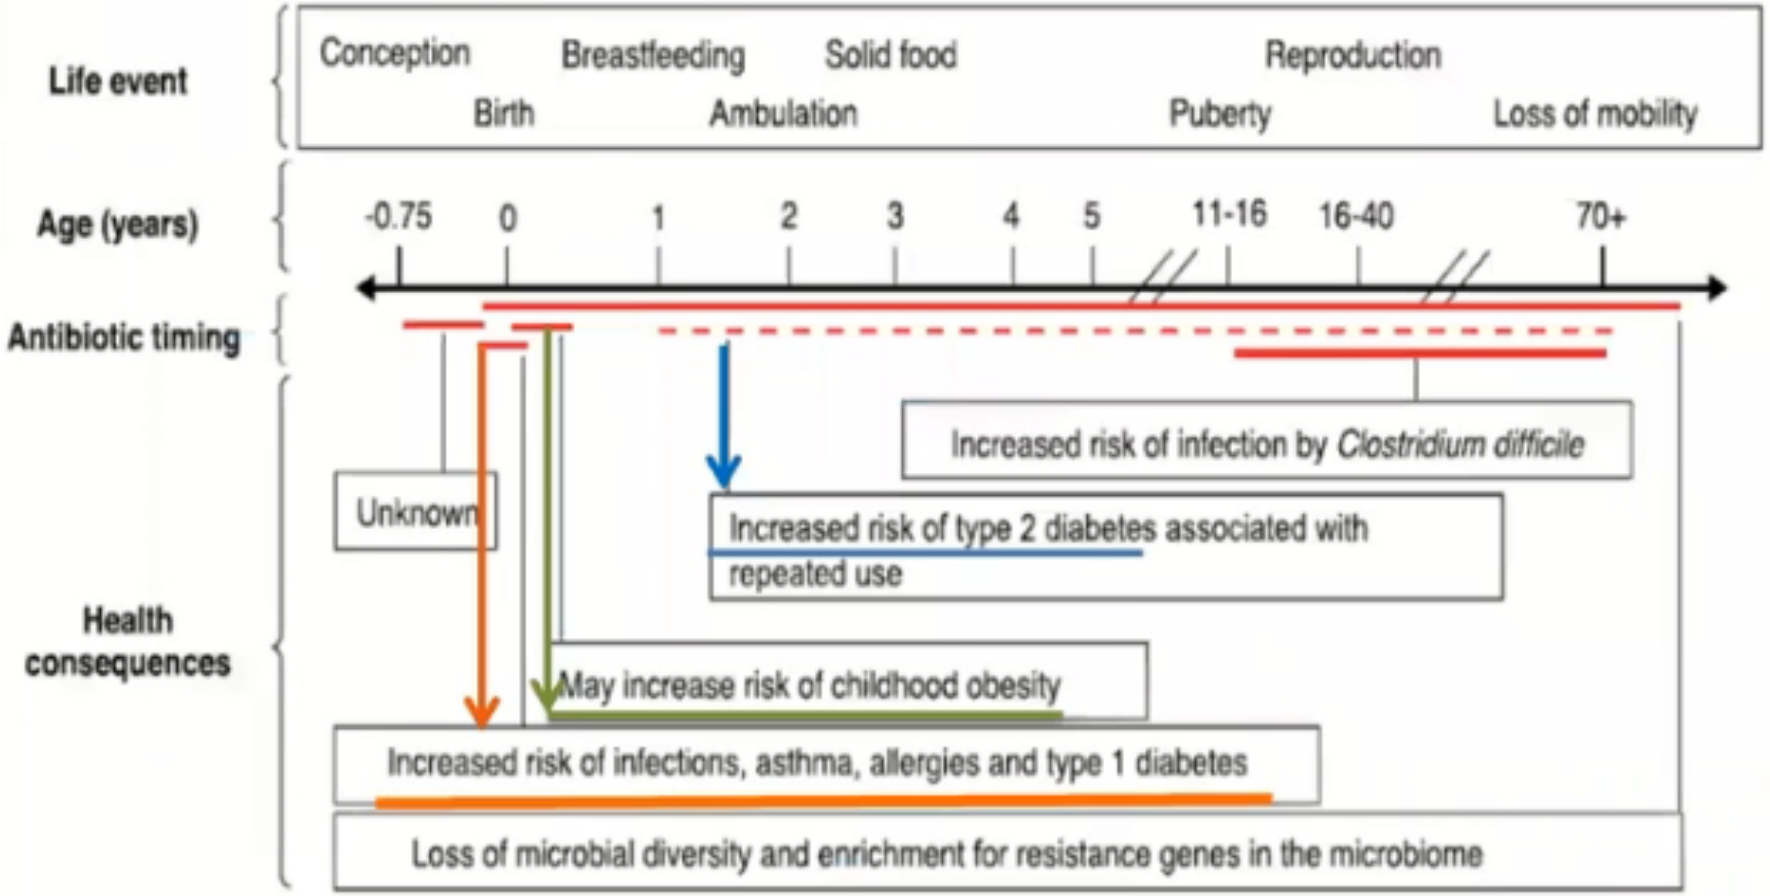
The effects of antibiotics on the microbiome throughout development and alternative approaches for therapeutic modulation



- In the long-term, infant antibiotic treatment is associated with childhood asthma and obesity (Azad et al., 2014; Penders et al., 2011), conditions also linked to gut dysbiosis in early life (Penders et al., 2007; Vael et al., 2011).
- In the preterm context (mean gestational age of 30 weeks, primarily CS birth and hospitalisation for 50 days), Arboleya et al. (2015) observed several changes to gut microbial composition following maternal IAP.

A total of 4.030 records were encountered. A total of 24 articles were included in the final anal- ysis. Infants from mothers exposed to antibiotics during delivery showed a decreased microbial diversity compared to non-exposed infants. The microbiota of infants exposed to antibiotics was characterised by a decreased abundance of *Bacteriodetes and Bifidobacteria , with a concurrent increase of Proteobacteria . These effects were most pronounced in term vaginally born infants.*

La sepsi neonatale è una infezione sistemica grave che può comportare non solo un esito infausto ma anche disabilità, morte precoce da disabilità, alterato sviluppo psicomotorio.
L'infezione materna a sua volta può comportare esiti negativi anche per le madri.

Si distingue in Early Onset (EOS), ad esordio nelle prime 72h (o 7 giorni) di vita e Late Onset (LOS) dopo le 72h (o 7 giorni)

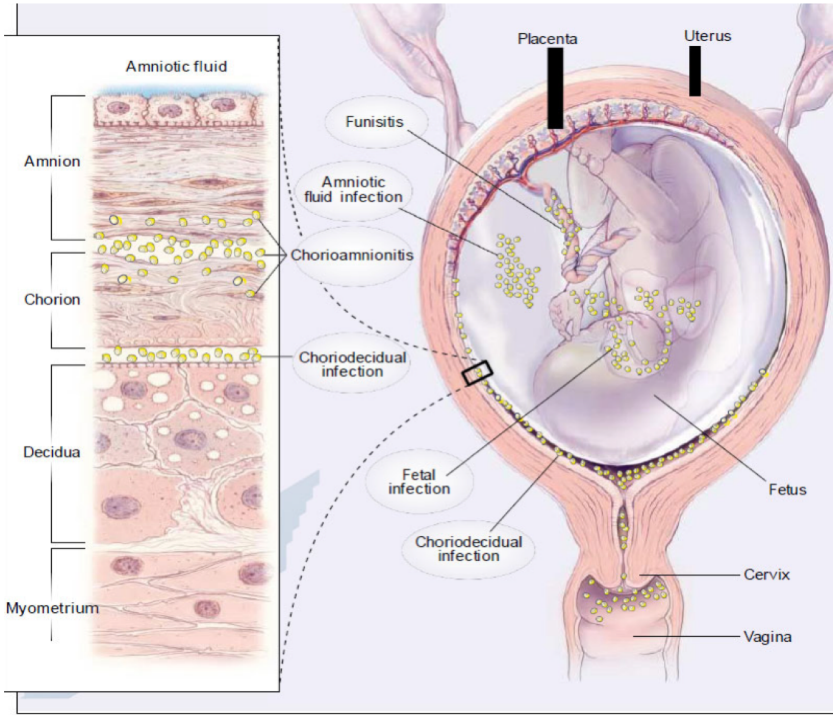
Le vie di trasmissione di infezioni dalla madre al feto o al neonato sono molteplici

- durante la vita fetale tramite lo scambio tra tessuti materni e membrane fetali, all'interno delle membrane fetali (amnion e chorion), tramite la placenta o il cordone ombelicale.
- durante il passaggio del neonato nel canale del parto



Si stima che **nel mondo** si verifichino ogni anno 6.9 milioni di infezioni neonatali e 400.000 decessi (WHO 2016)

In Italia 135-315 neonati/anno e 8-10 decessi per sepsi neonatale (Berardi, Ped Inf Dis , 2017)

L'incidenza è maggiore nei late preterm e 10-15 volte maggiore negli early preterm

Raccomandazioni

- L'esecuzione dello screening dell'infezione da streptococco beta-emolitico gruppo B con tampone vaginale e rettale e terreno di coltura selettivo è raccomandata per tutte le donne a 36-37 settimane.
- Le donne in gravidanza con infezione da streptococco di gruppo B devono ricevere un trattamento antibiotico intraparto.

→ *Queste raccomandazioni attribuiscono valore alla possibilità di identificare, attraverso lo screening, le donne nelle quali il trattamento antibiotico intraparto è potenzialmente in grado di ridurre una infezione neonatale da SGB a esordio precoce* (early onset GBS infection) *e alla possibilità di ridurre il numero delle donne che arrivano al parto con tampone eseguito da oltre 5 settimane (considerato l'intervallo ottimale), considerando che comunque, prima delle 37 settimane compiute, vi è indicazione alla profilassi antibiotica intraparto indipendentemente dal risultato del test.*

Management of Infants at Risk for Group B Streptococcal Disease

Karen M. Puopolo, MD, PhD, FAAP,[a,b] Ruth Lynfield, MD, FAAP,[c] James J. Cummings, MD, MS, FAAP,[d] COMMITTEE ON FETUS AND NEWBORN, COMMITTEE ON INFECTIOUS DISEASES

Group B streptococcal (GBS) infection remains the most common cause of neonatal early-onset sepsis and a significant cause of late-onset sepsis among young infants. Administration of intrapartum antibiotic prophylaxis is the only currently available effective strategy for the prevention of perinatal GBS early-onset disease, and there is no effective approach for the prevention of late-onset disease. The American Academy of Pediatrics joins with the American College of Obstetricians and Gynecologists to reaffirm the use of universal antenatal microbiologic-based testing for the detection of maternal GBS colonization to facilitate appropriate administration of intrapartum antibiotic prophylaxis. The purpose of this clinical report is to provide neonatal clinicians with updated information regarding the epidemiology of GBS disease as well current recommendations for the evaluation of newborn infants at risk for GBS disease and for treatment of those with confirmed GBS infection. This clinical report is endorsed by the American College of Obstetricians and Gynecologists (ACOG), July 2019, and should be construed as ACOG clinical guidance.

Take home messages

- La sepsi neonatale a esordio precoce (EOS) è una patologia con possibili gravi conseguenze per il neonato e per la madre, con incidenza tuttora rilevante
- E' necessaria la combinazione di strategie di competenza ostetrica e neonatologica
- Lo screening universale di tutte le gravide tra la 36-37+6 settimane resta una raccomandazione forte
- Le più recenti Raccomandazioni per la diagnosi precoce nel neonato sono basate sulla osservazione clinica intensiva supportata dall'utilizzo di sistemi di punteggio, al fine di effettuare accertamenti diagnostici e terapie antibiotiche solo per i soggetti per i quali siano effettivamente necessarie
- Interventi di profilassi primaria dell'infezione da GBS sono in fase sperimentale e potrebbero offrire un valido strumento

200÷250 m²

L'enorme importanza dell'intestino negli equilibri immunitari dell'organismo era già stata intuita da Ippocrate nel 2.500 a**.C. circa, al punto da spingerlo ad affermare che: "Tutte le malattie cominciano nell'intestino".**

Oggi sappiamo che l'intestino rappresenta uno dei più importanti baluardi immunitari dell'organismo.
Basti pensare che con la sua superficie di circa trecento metri quadrati, quest'organo ospita qualcosa come centomila miliardi di microrganismi e produce grossomodo il 60-70% delle cellule immunitarie dell'organismo.

A livello intestinale, infatti, sono presenti sistemi immunitari di **tipo innato (o aspecifico) e adattivo (o specifico)** che garantiscono una corretta risposta della mucosa intestinale in seguito all'ingresso di tutto ciò che viene riconosciuto come estraneo e pericoloso

Il fatto che i circa 100 trilioni di microrganismi appartenenti al microbiota non vengano attaccati dal nostro SI, al contrario di quanto avviene per i microbi patogeni, si deve alla complessa e dinamica interazione evolutasi nell'arco di quasi 500 milioni di anni, proprio tra questi speciali microrganismi e l'essere umano.

Questa interazione ha portato il sistema immunitario e il microbiota intestinale ad un adattamento reciproco molto vantaggioso per la nostra salute.

Le principali funzioni del microbiota intestinale

- Barriera contro la proliferazione dei patogeni, con un meccanismo noto come "*colonization resistance*" o "***effetto barriera***" o "***esclusione competitiva***". È il meccanismo utilizzato dai batteri già presenti nell'intestino per mantenere la loro presenza in questo ambiente, evitando la colonizzazione degli stessi siti intestinali da parte di altri microrganismi, ingeriti o già presenti
- Regolazione della maturazione del sistema immunitario e sua modulazione
- Produzione di vitamine (acido folico, vit. K, vit. del gruppo B)
- Regolazione della motilità intestinale
- **Parziale recupero di energia dalle fibre alimentari**

Il microbiota intestinale potrebbe essere inteso come un organo metabolicamente attivo del corpo umano

"It seems appropriate to consider ourselves as a composite of many species - human, bacterial, and archaeal - and our genome as an amalgamation of human genes and the genes in 'our' microbial genomes ('microbiome')"
Human Gut Microbiome Initiative (HGMI)

Durante la vita la mucosa intestinale viene a contatto con un numero incalcolabile di antigeni (batteri, virus, parassiti, antigeni alimentari, farmaci e diversi altri composti chimici); pertanto è di fondamentale importanza la presenza di difese che assicurino un’adeguata protezione.

Questo sistema complessivamente prende il nome di **barriera intestinale**.
Una parte fondamentale di questo effetto barriera viene svolto dal tessuto linfoide associato all'intestino (**GALT**), costituito prevalentemente da linfociti T, che costituiscono circa un sesto delle cellule dei villi, da linfociti B, cellule dendritiche e plasmacellule (secernenti prevalentemente **Ig A**) presenti nel connettivo della lamina propria e da follicoli linfatici isolati (più frequenti nel colon) o aggregati (placche del Peyer, nell'ileo).

TECNICHE DI SEQUENZIAMENTO GENOMICO

Mediante l'uso del gene 16 SrRNA, unico per ora che identifica i procarioti quali sono i nostri batteri intestinali.

Le tecniche genomiche hanno permesso di:

- Identificare altre popolazioni batteriche presenti nell'intestino
- Di raggruppare in Phylum (tribù) gli ordini e le specie

I Phylum sono inferiore al Regno e superiori alla Classe e si identificano in Ordini e Specie che raggruppati hanno caratteristiche comuni.

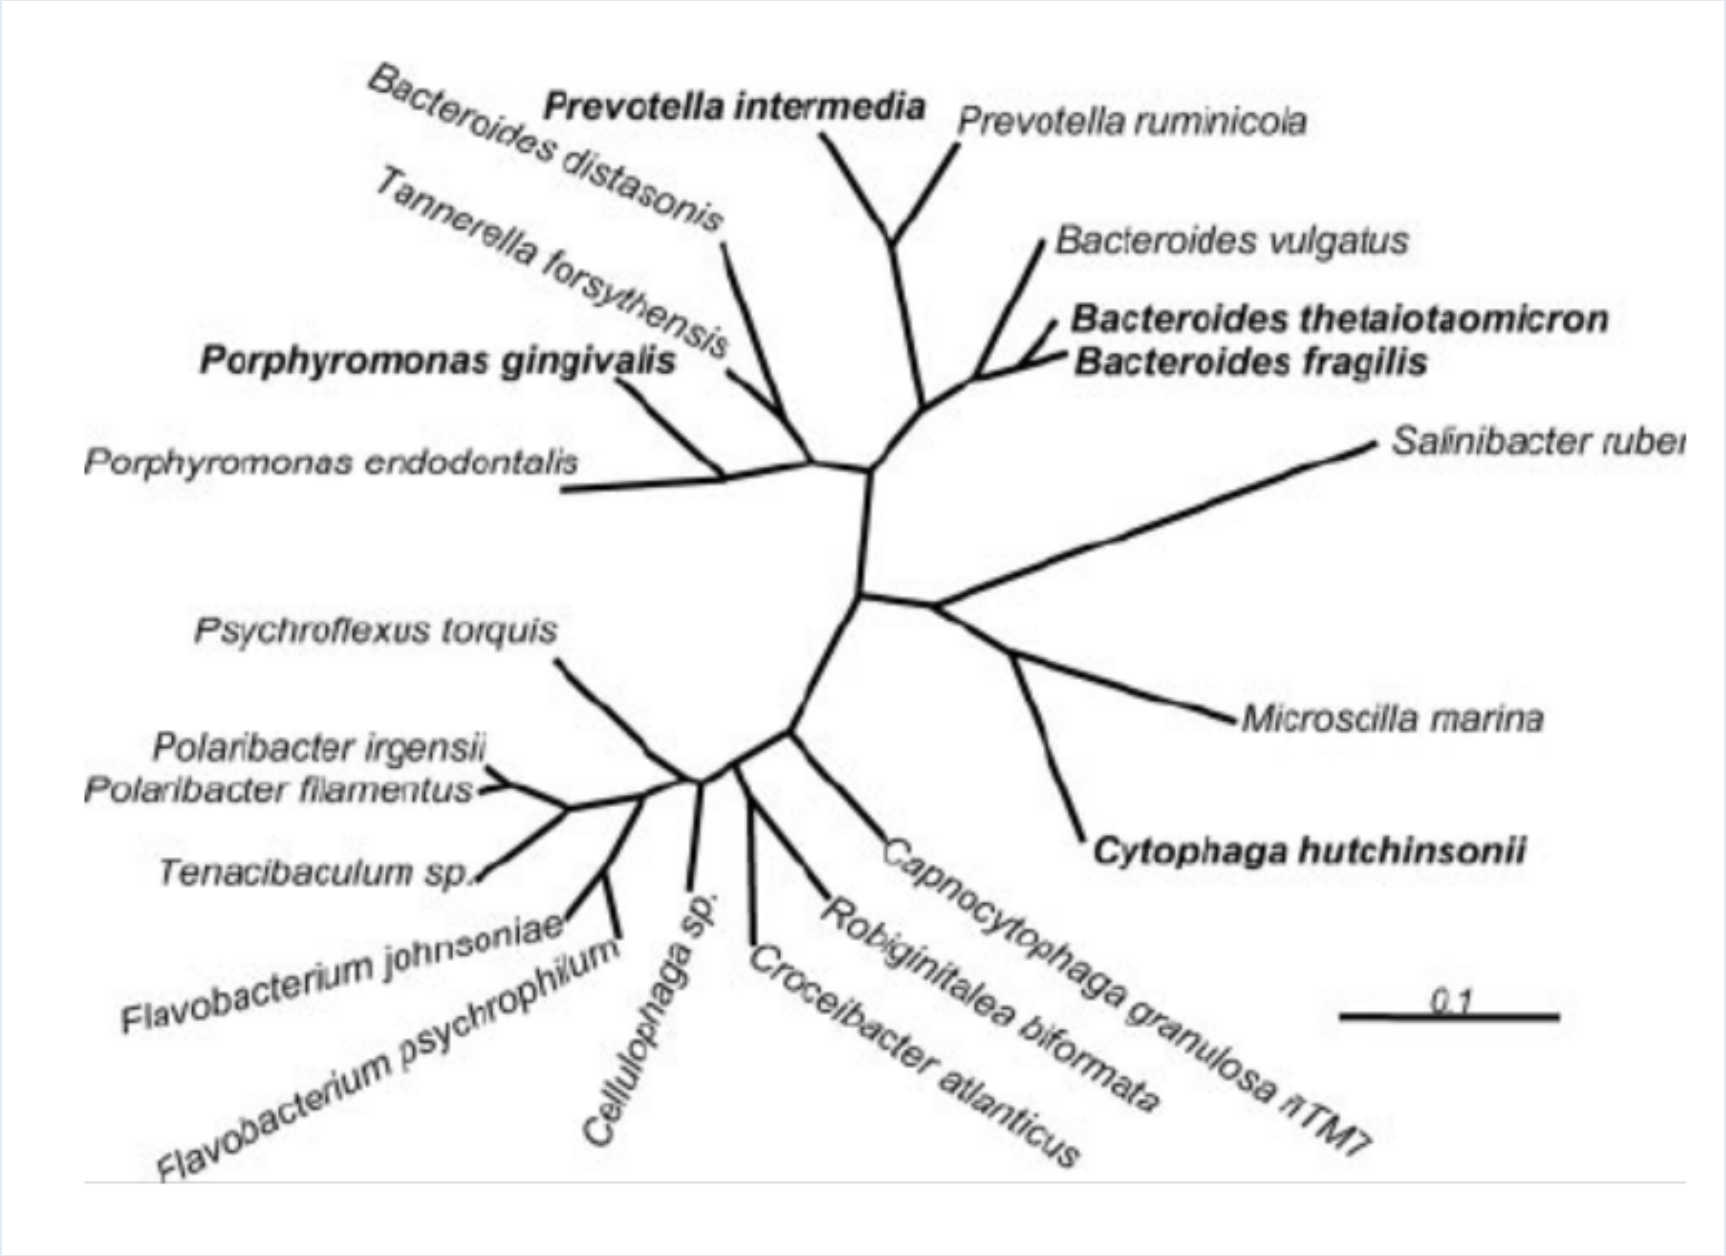
Bacterioidetes



Firmicutes

Questi batteri sono dei gram-positivi che, insieme ai Bacteroides, abitano normalmente nel colon umano e sono naturali ospiti della flora microbica normale. Recenti studi dimostrano che hanno un'implicazione nell'assorbimento del glucosio, di conseguenza l'obesità potrebbe essere un fattore derivante da una flora batterica disbiotica e quindi potrebbe curarsi agendo su quest'ultima.

I Phylum Firmicutes comprende 274 generi tra cui:

Bacilli

- *Bacillus*
- *Listeria*
- *Lactobacillus*

Cocchi

- *Lactococcus*
- *Micrococcus*
- *Staphylococcus*
- *Streptococcus*
- *Sarcina*
- *Peptococcus*
- *Peptostreptococcus*

Clostridia

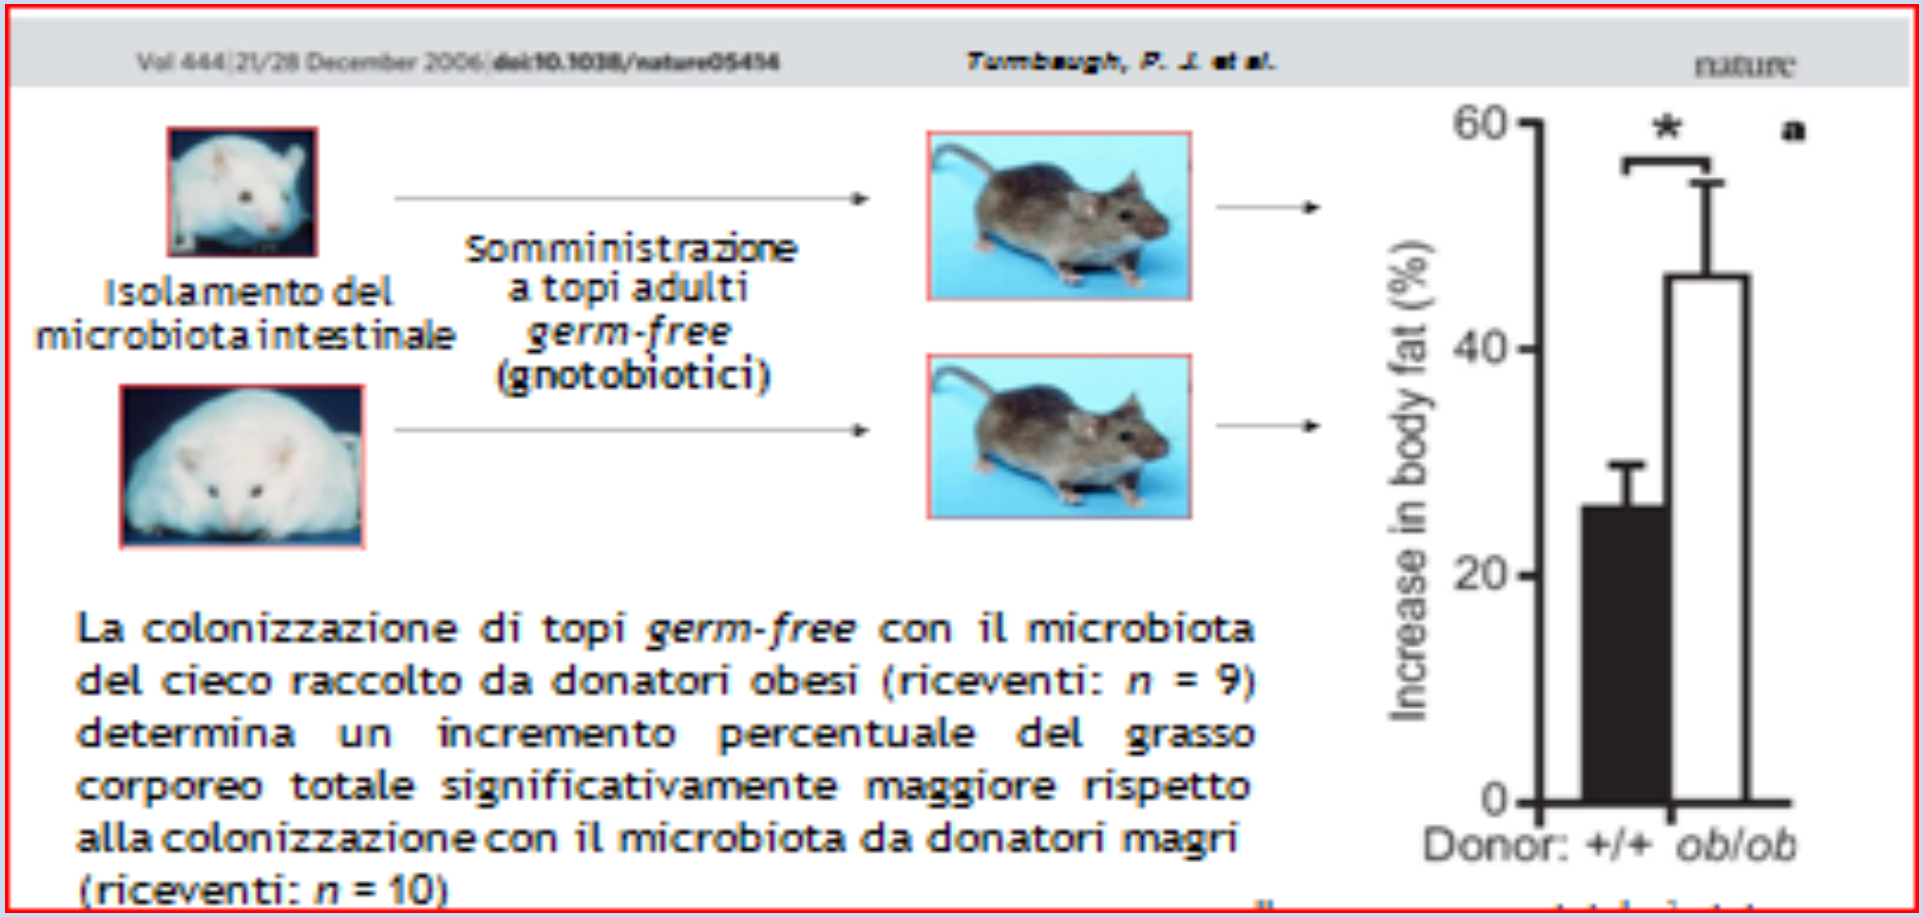
Rapporto standard tra

Firmicutes / Bacterioidites = 0,8

Se aumentano i Firmicutes andiamo incontro a obesità,

Se diminuiscono andiamo incontro ad infiammazione intestinale

I Bacterioidites proteggono dall'obesità non dal diabete



Il microbiota intestinale associato all'obesità ha una maggiore (e trasmissibile) capacità di indurre l'accumulo di grasso

FUNZIONE IMMUNOMODULATORIA

I batteri intestinali svolgono un ruolo essenziale nello sviluppo del sistema immune.
L'induzione e la regolazione del sistema immune avviene a livello del piccolo intestino.
Un disequilibrio della flora batterica intestinale conduce una inadeguata risposta del sistema immune che over-reagisce con gli antigeni esterni ed è responsabile dell'insorgenza di alterazioni locali e sistemiche.
Si ritiene che nelle forme di intolleranza e allergia alimentare la flora batterica intestinale possa svolgere un ruolo chiave in quanto induce una risposta iperimmune nei confronti degli antigeni alimentari.

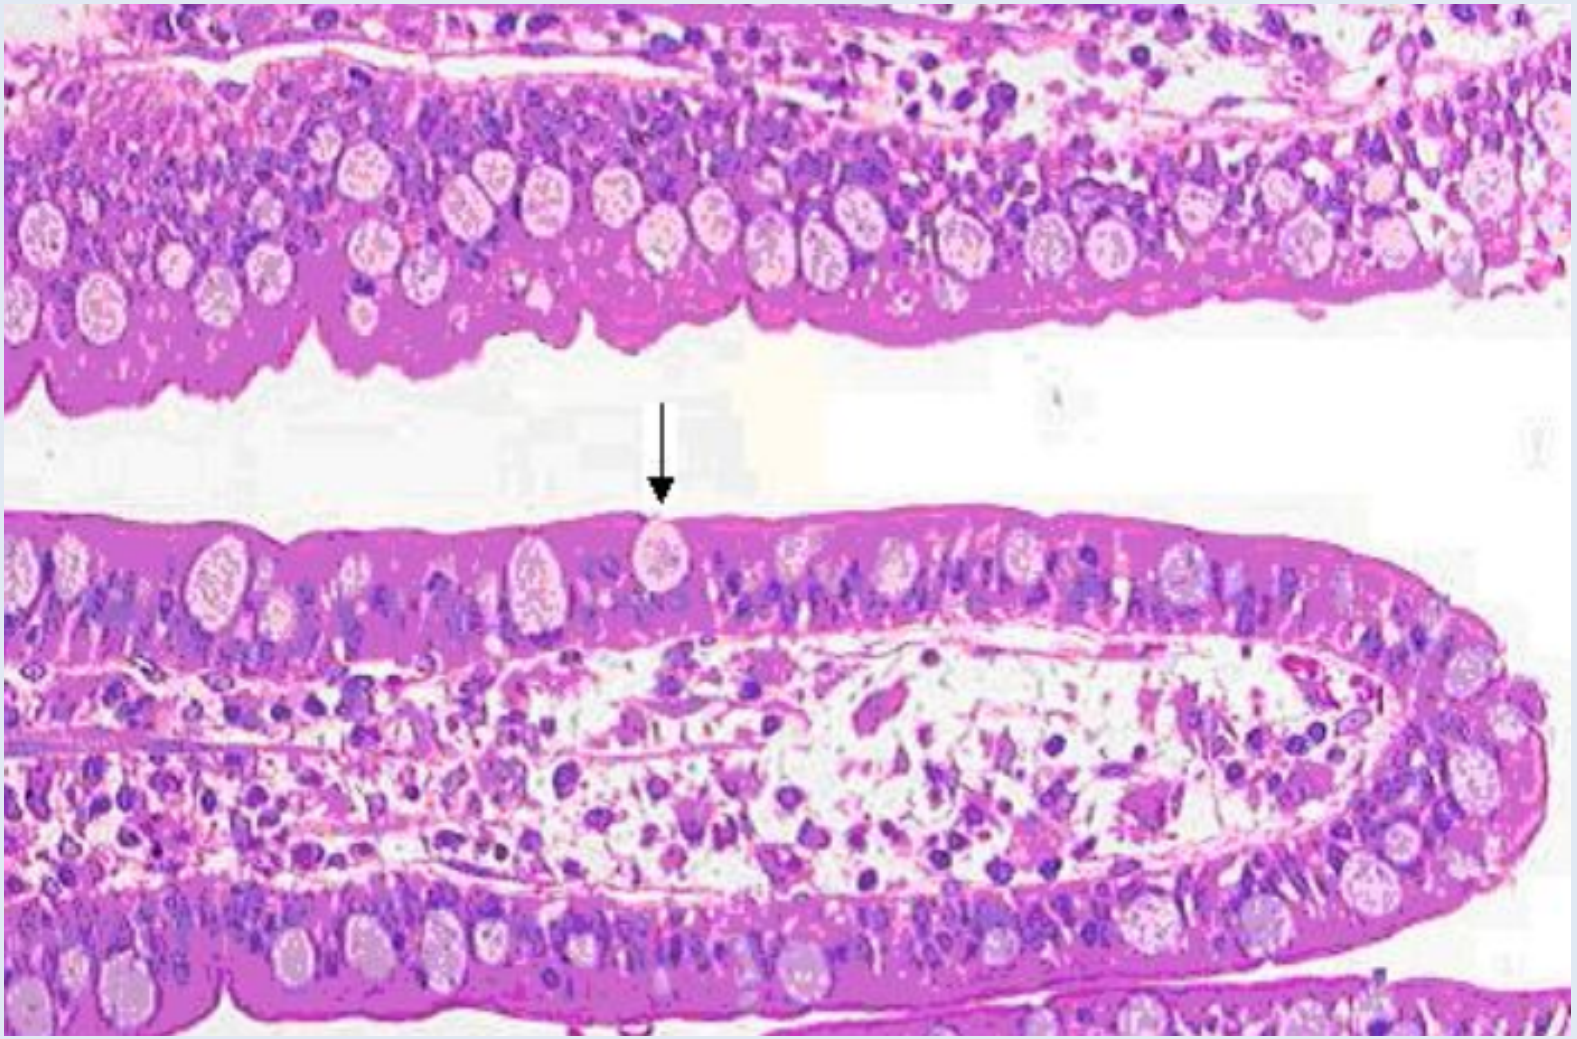
MUCO

Il microbiota è separato dalle cellule epiteliali da una rete di GLICANI (muco) prodotti dalle cellule mucipare intervallate dalle cellule epiteliali.

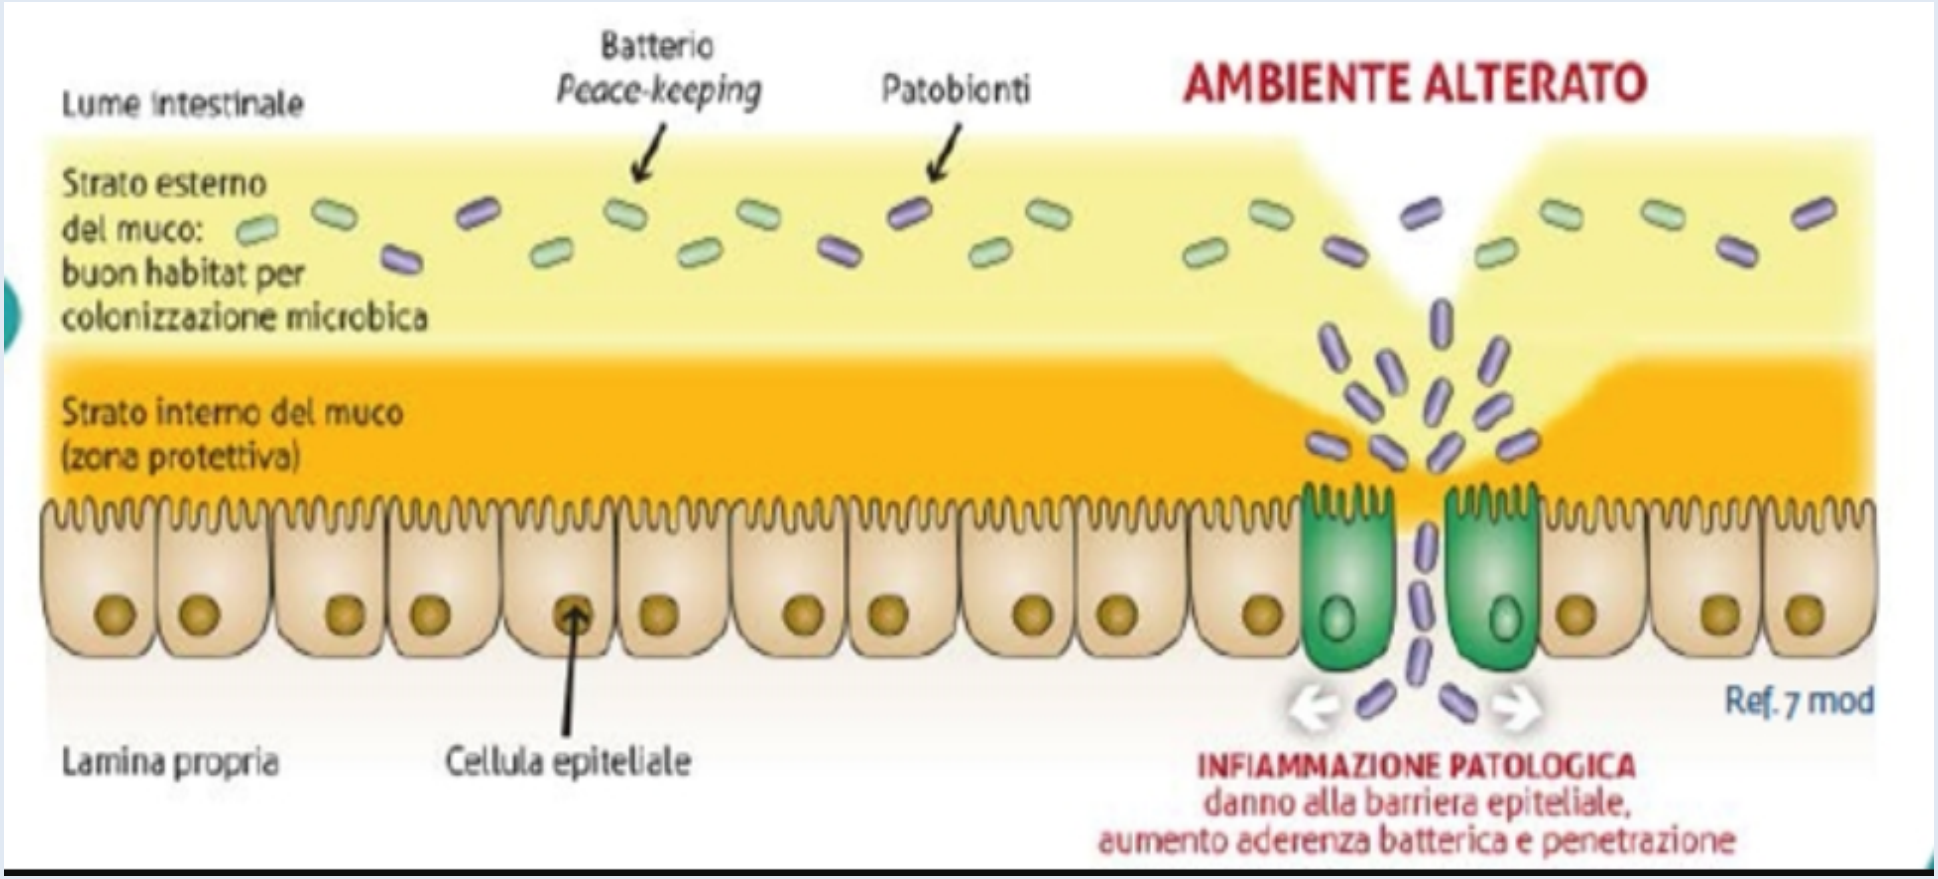
Lo strato di muco è essenziale per assicurare l'integrità della parete intestinale.

La produzione giornaliera di muco è di circa 5 litri.

CELLULA MUCIPARA



ALTERAZIONE DEL MUCO



Il microbiota contribuisce alla produzione di muco ed allo spessore dello strato mucoso.

Questo avviene in parte per la stimolazione della sintesi di Mucina da parte di alcuni componenti di sintesi batterica quali SCFA (acido butirrico acetico, propionico).

TRASLOCAZIONE BATTERICA

La condizione di disbiosi porta ad una disfunzione indiretta quindi non primaria, ma secondaria, della BARRIERA EPITELIALE INTESTINALE che crea una via di ingresso nell'organismo tramite il sangue di batteri, dando origine a fenomeni di

ZONULINA

La individuazione della Zonulina avviene nel 2000 ad opera di A. Fasano, a capo della ricerca presso L'Università del Maryland Celiac Research Center, e del suo team presso l'Università del Maryland School of Medicine.

Ruolo della zonulina nelle modificazioni della permeabilità intestinale tipiche della fase acuta della malattia celiaca

La gliadina rappresenta il primo ambito della ricerca che ha potuto mettere a fuoco il ruolo della zonulina sulla giunzione serrature. Il glutine influisce direttamente sulla mucosa intestinale favorendo la produzione di zonulina. E' una proteina che regola le giunzioni delle pareti intestinali e, se in eccesso, le allenta favorendo uno stato di permeabilità intestinale.

Zonulin, a regulator of epithelial and endothelial barrier functions, and its involvement in chronic inflammatory diseases.

Sturgeon C[1], Fasano A[2].

Alcuni studi hanno evidenziato come la disbiosi del microbioma può causare il rilascio di zonulina che porta al passaggio di contenuti endoluminali attraverso la barriera epiteliale con conseguente rilascio di citochine pro infiammatorie.

I valori della zonulina possono rappresentare il parametro di riferimento per la classificazione dell'entità dell'alterazione della mucosa intestinale e conseguente stato di permeabilità.

I valori riscontrati sono significativi dello stato infiammatorio in atto e correlabili con i sintomi clinici.

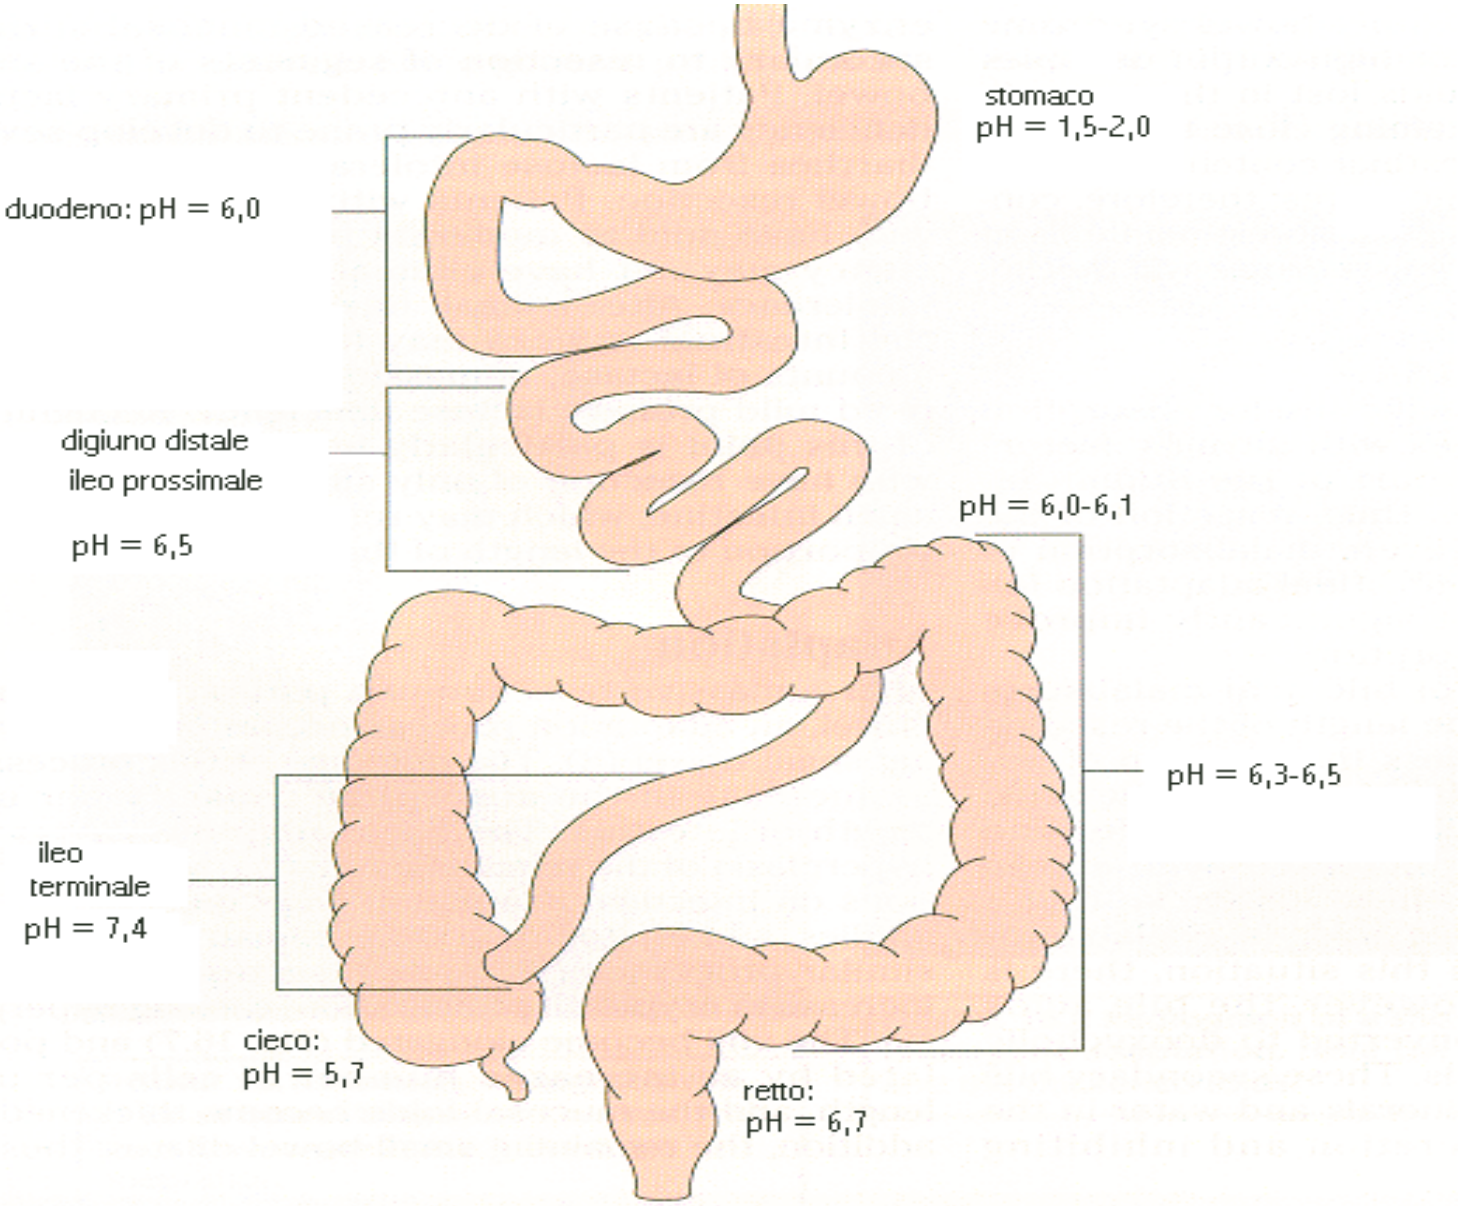
IL PH NEI SINGOLI DISTRETTI



PH *INTESTINALE*

Il Ph del colon ha un marcato effetto nella composizione delle specie batteriche presenti.

Walher et al (2005) hanno dimostrato una correlazione tra cambiamento nella composizione della specie dei microrganismi da:

- Ph 5.5 dove i batteri formanti butirrato sono il 20%
- Mentre a Ph 6.5 questo gruppo diventa impercettibile

PH *INTESTINALE*

- A Ph 6.5 la comunità dei fermentatori è dominata dai BACTEROIDI gram- patogeni.

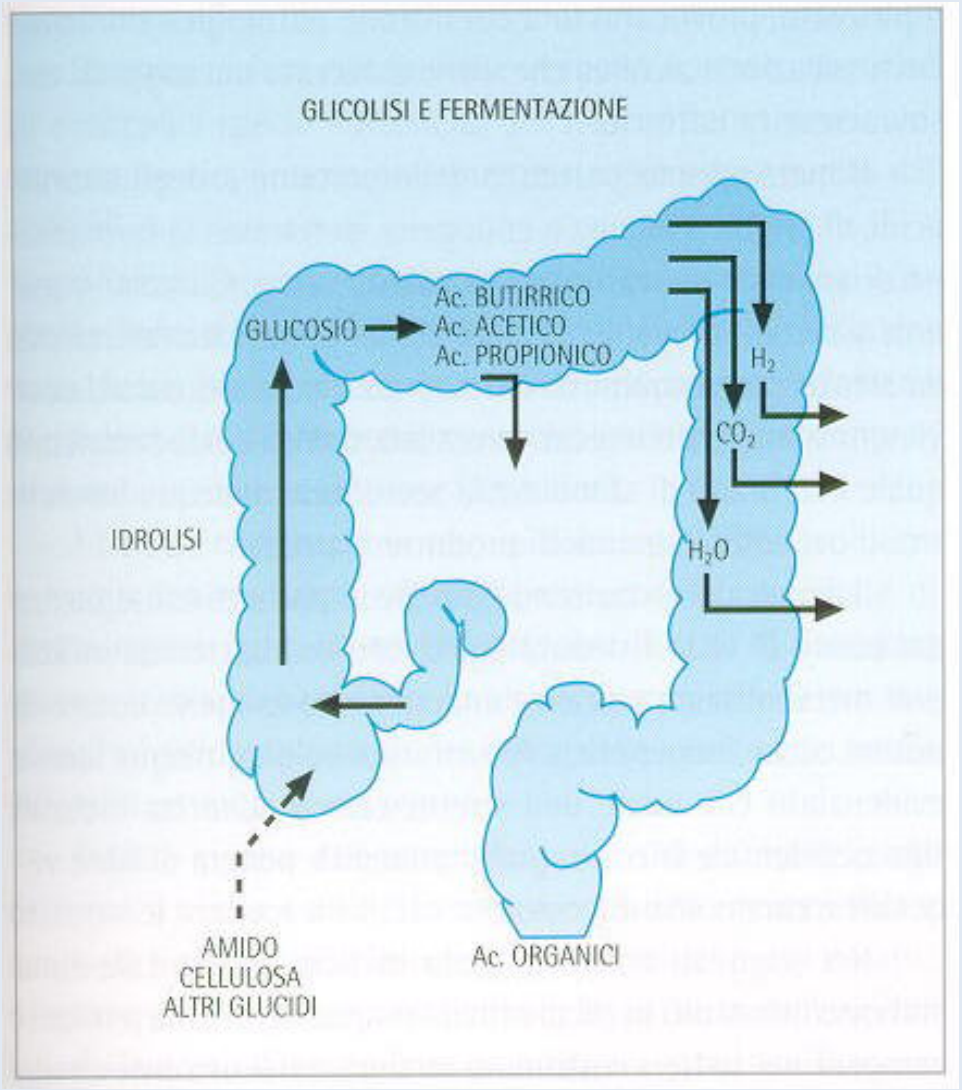
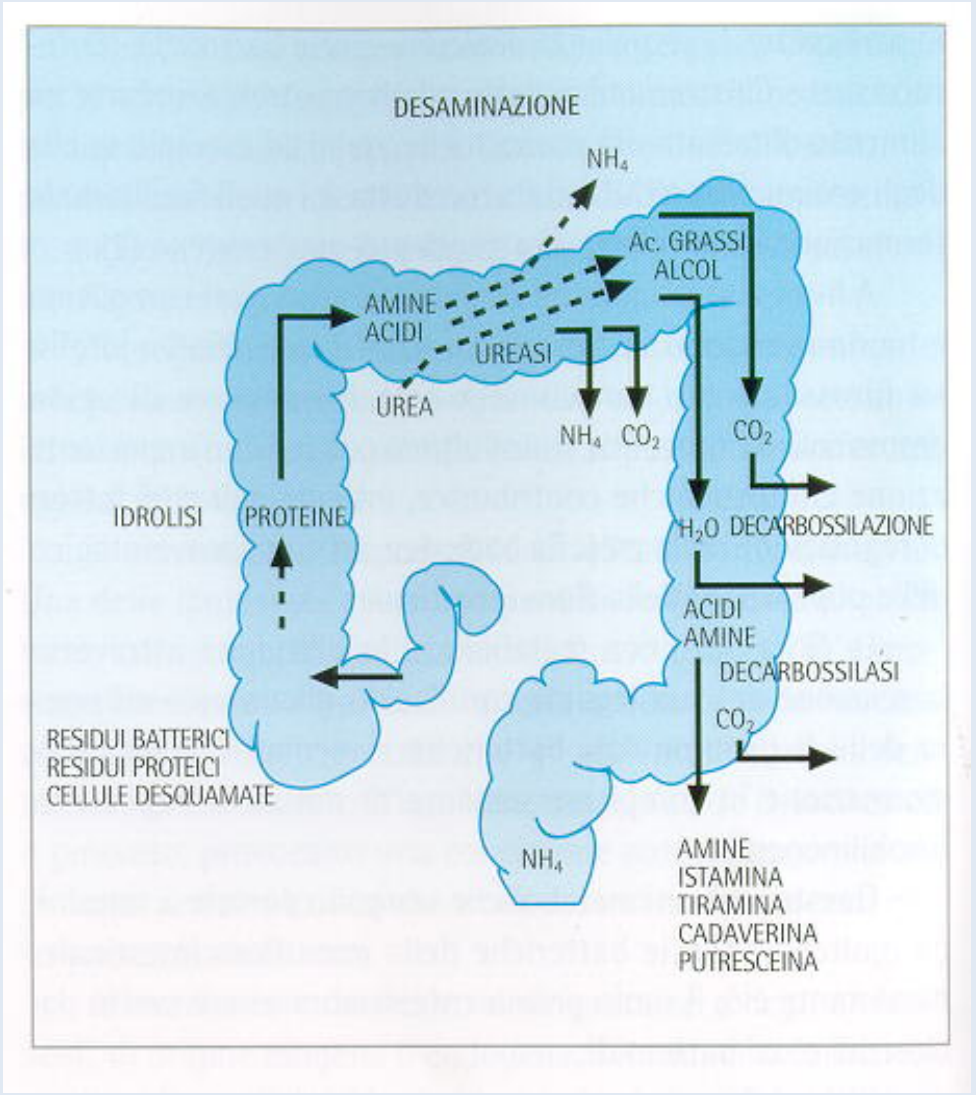
LA FLORA FERMENTATIVA E PUTREFATTIVA





LA FLORA fermentativa

La fonte principale di carbonio e di energia per i batteri è costituita da carboidrati complessi (amido e altri polisaccaridi).
Il metabolismo dei carboidrati è di grande importanza a livello del grosso intestino, dato che i microrganismi sono prevalentemente *saccarolitici.*

La **fermentazione** è una reazione anaerobia nella quale le molecole di piruvato al posto di essere degradate nei mitocondri, rimangono nel citosol e – nel caso dei lieviti- vengono convertiti a **etanolo e CO_2**.

In mancanza di carboidrati fermentabili o in caso di aumentata presenza di proteine per una dieta ricca in grassi e carne e a basso contenuto in fibre la flora attua una degradazione enzimatica delle proteine e degli aminoacidi, detta **fermentazione proteica** o **putrefazione** con produzione di **ammonio e amine**.

LA FLORA Putrefattiva

La fermentazione proteica o *putrefazione* comporta
• un' aumentata concentrazione di Batteriodi
• aumento del pH fecale per aumento dell'ammonio fecale e con
• formazione di un certo numero di metaboliti potenzialmente tossici, ovvero di **fenoli, indoli e amine**.

• L'entità della fermentazione proteica si misura **dall'eliminazione urinaria di fenolo e di p-cresolo.**
• La produzione di queste sostanze è inibita o soppressa in molti microrganismi intestinali in caso di disponibilità di un substrato fermentabile di carboidrati *(6).*
• I processi putrefattivi diventano invece quantitativamente più **importanti nel colon distale**, ove i carboidrati fermentabili sono più scarsi. *(6)*

La disbiosi intestinale

Definizione

Disbiosi è **uno stato di alterata ecologia della microflora che causa malattia.**
Può esistere a livello del cavo orale, del tratto gastroenterico e in vagina.
Il termine *disbiosi intestinale* tende a sostituire quello più vecchio di dismicrobismo e a cui si contrappone il termine di eubiosi.

In caso di disbiosi, organismi a bassa virulenza intrinseca, quali batteri, lieviti e protozoi, possono indurre malattie mediante alterazioni dello stato nutrizionale o la risposta immune dell'ospite *(9)*
Un'alterazione di quest'ecosistema può comportare importanti conseguenze sullo stato di salute con sintomi o patologie sia locali che sistemici.

La disbiosi **può interessare sia il tenue che il grosso intestino**, per cui il termine disbiosi non è da intendere come sinonimo di sovraccrescita batterica, la quale interessa soltanto il piccolo intestino, e che ne è quindi una delle forme possibili.

DALLA CAPACITA’ DI ADERENZA DEL GBS

SUGLI EPITELI

Le condizioni ambientali dell'ospite sono determinanti per lo sviluppo del biofilm batterico:

Una maggiore aderenza del GBS alle cellule epiteliali vaginali si verifica maggiormente in ambiente a PH neutro rispetto a un PH acido

La rigida struttura della parete cellulare caratteristica dei batteri Gram positivi consente loro di sopravvivere in ambiente ipotonico, modulando l’assunzione di acqua dall’esterno tale da impedire la lisi cellulare

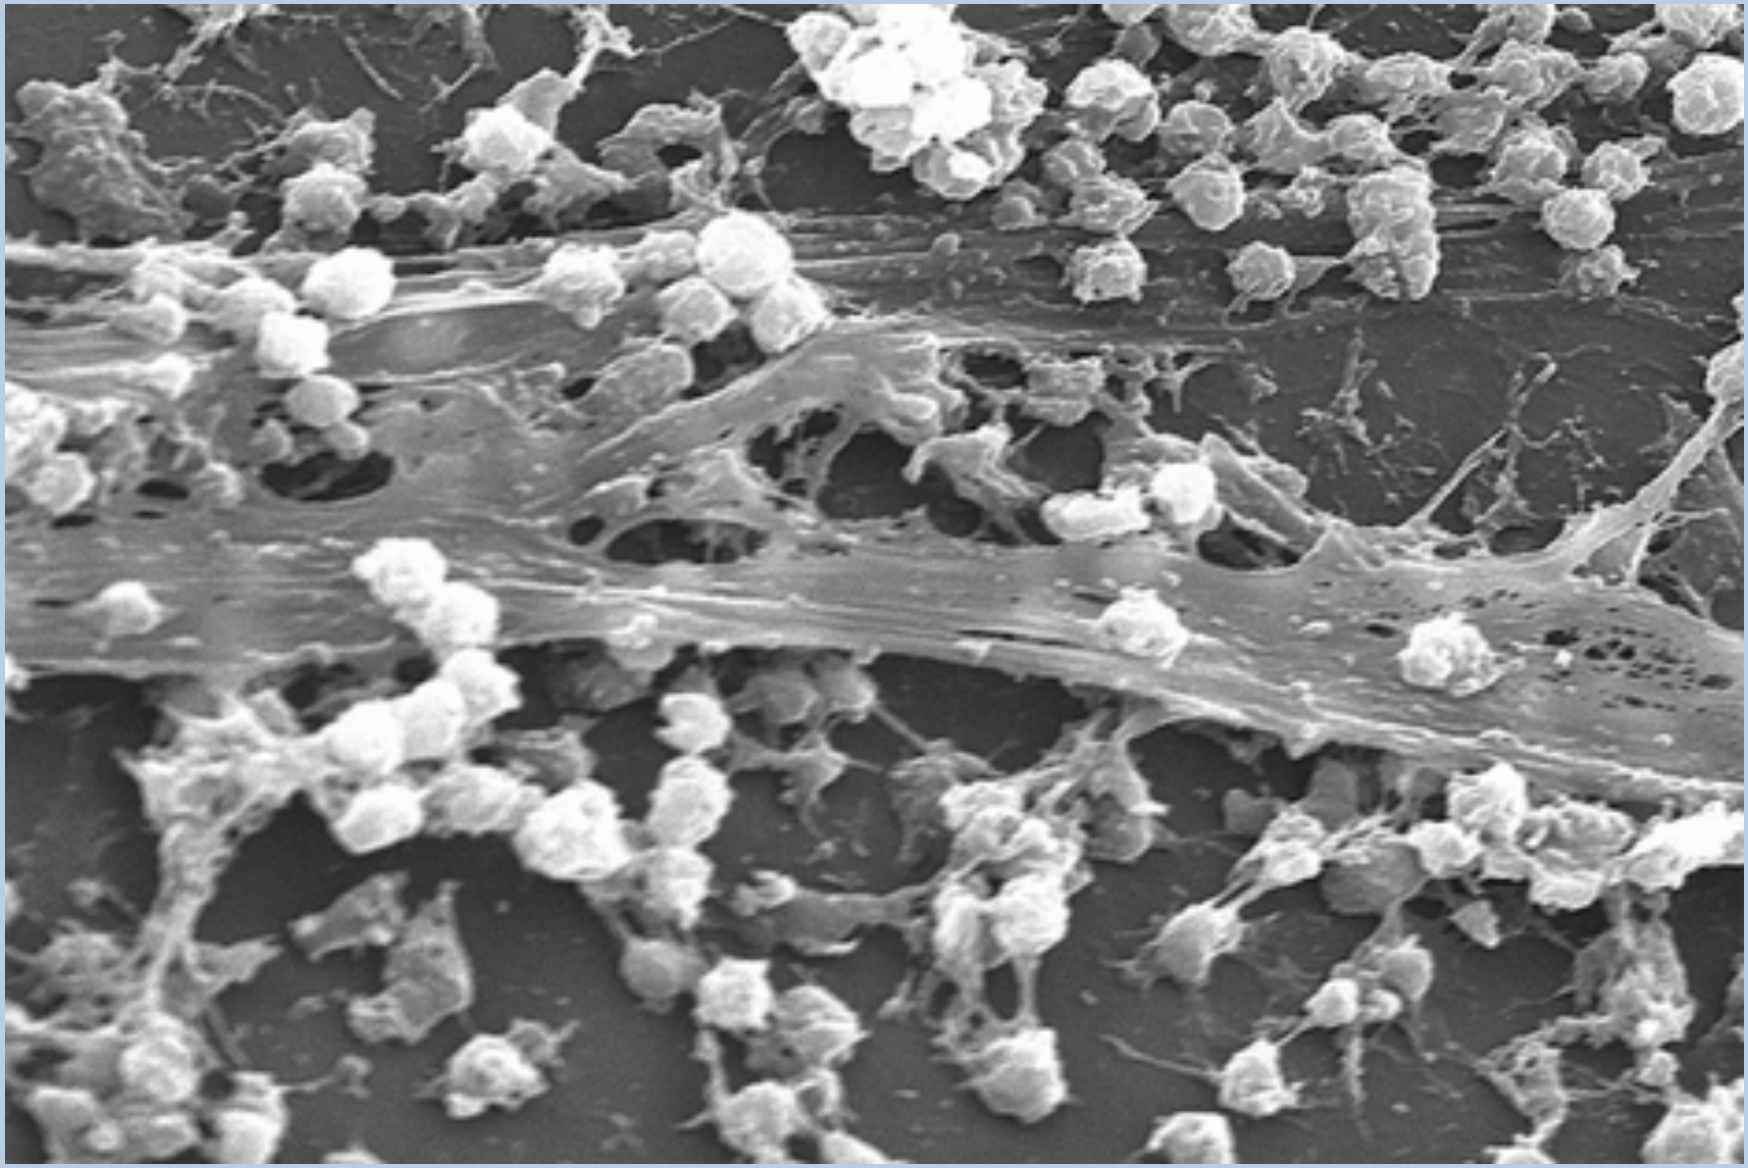
Il GBS presenta una capacità di adesione sia sulla matrice extra cellulare che sulle cellule ospiti svolta da una ADESINA BiBA

In grado di interferire con le proteine del COMPLEMENTO e inibire la fagocitosi neutrofila

Nell’ultimo decennio sono state scoperte strutture filamentose nel GBS che potrebbero esprimere un ulteriore ruolo nella adesione cellulare e nella colonizzazione e infezione dell’ospite.

Queste strutture favoriscono la formazione del biofilm



La presenza di pili e la formazione di Biofilm ha permesso di identificare un sottogruppo di ceppi del sierotipo III (tipo ST-17) in grado di formare biofilm più resistenti di altri e di essere la causa più frequenti di infezioni neonatali ad esordio tardivo

Bacterial glycobiology: rhamnose-containing cell wall polysaccharides in Gram-positive bacteria

Michel-Yves Mistou [1], Iain C Sutcliffe [2], Nina M van Sorge [3]

Le variazioni della struttura del polisaccaride capsulare hanno determinato 10 varianti antigeniche ad oggi conosciute. In generale la capsula è composta da unità ripetute di glucosio, galattosio, ramnosio, N-acetilglucosammina, acido sialico.

Nei sierotipi Ia, Ib e III lo zucchero terminale è rappresentato dall'acido sialico che gioca un ruolo importante nella virulenza.

Infatti la rimozione di questo residuo porta ad una perdita di virulenza nel modello del ratto neonato e un aumentata fagocitosi da parte dei neutrofili umani.

L’adesione e la colonizzazione del GBS è un complesso multifattoriale che porta al mantenimento del patobionte nell’ecosistema umano.

Il GBS possiede rigidi sistemi che favoriscono il suo mantenimento.

La colonizzazione e la persistenza dipendono anche dalla qualità del microbiota vaginale e intestinale.
